Primary bundles.—As seen in transverse section, there are many small xylem strands embedded in the pith (fig. 11), all of which are submarginal in position. None are truly medullary such as have been described for Pitys (Scott, 1902) and Archaeopitys (Scott and Jeffrey, 1914). They are irregularly spaced, some are single, others occur in groups of three or four, and in some instances two or three distinct tracheid groups lie on the same radial plane. Many of the strands contain from two to four tracheid elements as seen in transverse section (fig. 13), and, where largest (near a node), they rarely have more than twenty cells (fig. 12). The larger bundles are tangentially elliptical.

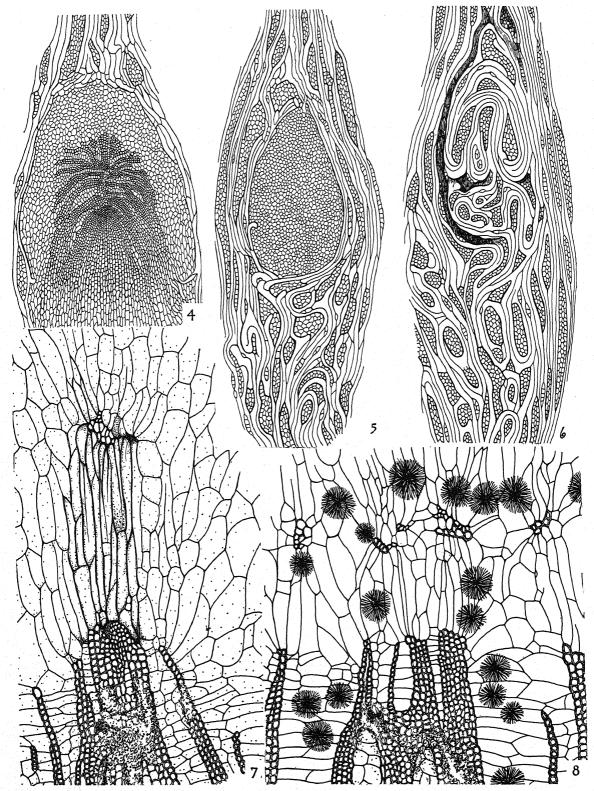

Fig. 4-8.—Fig. 4. Tangential section of secondary wood zone, showing emerging leaf trace cut transversely near its terminus. Secondary elements completely surround the primary wood. ×26.—Fig. 5. Tangential section of secondary wood cut about 1 mm. off the terminus of a leaf trace bundle. The general outline of the bundle persists in the mass of parenchyma. Tracheids on the abaxial side of the trace are much convoluted, and some of them are

A block 2.5 cm. long and 2.2 cm. wide was cut from the proximal end of the stem, and from it a series of eleven transverse sections were prepared to determine the course of primary bundles in the pith and their nodal relation to the paired leaf traces. Figure 2 is a diagram reconstructed from this series and shows approximately the course of primary bundles, except that it shows one only where two or more lie on the same radial plane. The figure represents the strands as seen from the center of the pith, so that the anodic direction or ascending spiral is toward the left. It is apparent that the strands diverged somewhat at the nodes, branched frequently, and connected with neighboring bundles. The two X symbols at the bottom of the figure mark the points of emergence of paired leaf traces which in section 11 are well out in the secondary wood, and the two above mark the position of the next pair of the same orthostichy. Although the two bundles in section 1 had not entered the secondary wood at that level, they were about to do so, as indicated by their size, shape, and the excessive elongation of pith cells between them and the secondary wood columns opposite. Included in the figure are three pairs of traces and four additional traces of other pairs.

Four bundle branches are formed at each node. Two are associated with each bundle. They are given off considerably below the node, one on the kathodic side and one on the anodic side of each bundle. The latter is a reparatory strand which continues apically, giving off one or two branches on the anodic side, and contributes to the correspending bundle which emerges at the next node of the same orthostichy (the thirty-fourth above). The branch which diverges on the kathodic side connects with the neighboring bundle by a diagonal anastomosis. There is this peculiarity in the arrangement due to the paired traces—the diagonal branch from the kathodic bundle of any pair contributes to the anodic member of the paired traces which emerge at the eighth node above, and that from the anodic bundle contributes to the kathodic member of the pair which pass out at the thirteenth node above. This diagonal connection therefore serves to join the anodic bundle of each pair with the kathodic member of the next pair of the same orthostichy and intercepts all branches within the distance of two superposed nodes. This arrangement appears to be a constant feature of the stem structure.

In the series of transverse sections, certain primary strands appear to be divided so that two or

more small xylem groups lie approximately on a radial plane. When traced upward or downward in the stem, these change their relative position and appear to connect again with the bundle or with the secondary wood. Radial sections confirm this evidence but are somewhat unsatisfactory because of the imperfect preservation and because the bundles follow a tortuous course.

Since the proximal end of the stem was fractured and subjected to weathering, and because of radial elongation of pith cells in the marginal zone, longitudinal-radial fractures could be made in this region of the stem. In this manner the nature of the slender xylem strands could be shown. They are seen to be branches from the primary bundles which connect with other branches, with the bundle at a higher level, or with the secondary wood. Figure 3 is a semi-diagrammatic restoration of this arrangement and was made from two fractures, one of which shows the bundle where it turns out from the pith to enter the wood zone as a leaf trace, and the other, from a lower level, includes the tangential divergence of reparatory and diagonal strands shown by the symbol (\*).

Since structural details are poorly preserved in the primary bundles, the identification of protoxylem elements is difficult, and must be determined largely by size rather than by wall sculpturing.

The bundles are largest near nodes where they contain about sixteen to twenty cells as seen in transverse section and appear in most instances to be endarch. In strands of four to eight elements the smaller cells may lie on the inner border, in a lateral position, or at the outer margin (fig. 8). The metaxylem elements are relatively small (average  $40 \mu$ ) and appear to be reticulate or transitional from reticulate to pitted. No distinctly pitted metaxylem can be observed.

A point of interest in the primary system pertains to the subsidiary branches or ramifications. Are they homologous with the true medullary strands of certain Pityeae (Scott, 1923) and of Archaeopitys (Scott and Jeffrey, 1914)? In the latter genus they are known to be branches given off by the primary bundles and have been described as developing centripetally and diverging upward. Whether or not they terminate in the pith or connect with other bundles at higher levels is not known. In this stem the small subsidiary branches tend to be radially aligned and in most instances lie between the primary bundle and secondary wood. They appear to be without protoxylem and never contain more than a few tracheids as seen in trans-

branched.  $\times 29$ .—Fig. 6. Tangential section of secondary wood cut about 2 mm. off the terminus of a leaf trace, showing the invasion of tracheids, convolutions, occasional branching of tracheids, and the short, rounded wood rays. The dark, curved column outlines one side of the gap which is here occluded with tracheids and distorted rays.  $\times 29$ .—Fig. 7. A transverse section cut at the point where the submarginal bundle is divided into radially aligned strands, one of which is in contact with secondary wood and the other is about to turn out. The two are connected by elongated pith cells. The outer strand appears to be endarch.  $\times 55$ .—Fig. 8. A transverse section cut below a node where the reparatory strand lies at the left (anodic position) and the diagonal strand at the right (kathodic position). The intervening bundle is composed of three tracheid groups. Note the variable position of protoxylem elements, the presence of spherulites, and dilation of rays.  $\times 55$ .

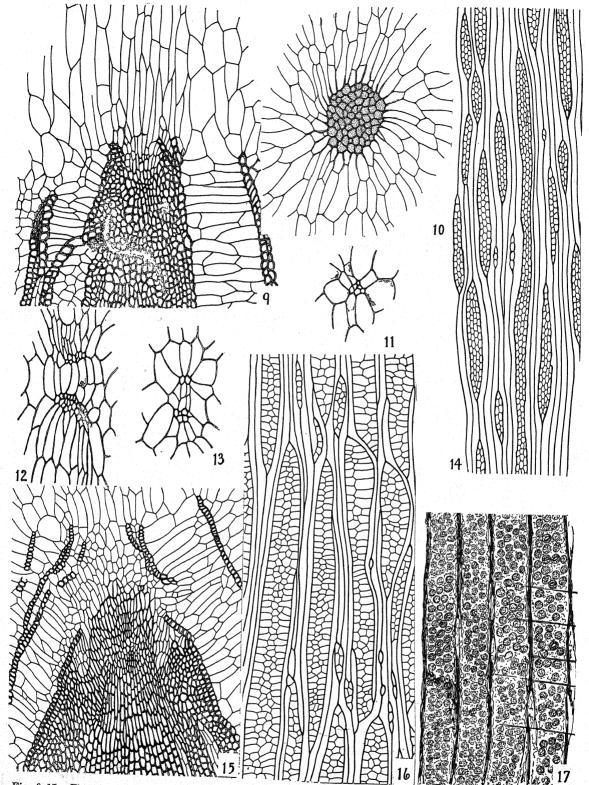

Fig. 9-17.—Fig. 9. Transverse section showing entrance of leaf trace into secondary wood. There are apparently two radially aligned protoxylem groups, cut at an angle and separated by larger elements. Secondary tracheids flank the primary xylem and close in behind the trace at higher levels. Pith is radially elongated opposite the trace. ×55.—Fig. 10. A radial section of pith and a sclerotic nest, showing the central mass of polyhedral cells and radially dis-

verse section. There is some resemblance to the medullary tracheids which in certain Calamopityeae have caused the central cylinder to be interpreted as being a modified protostele. In this instance, however, they are not isolated tracheid groups, since sections and fractures both show them to be continuous with the primary strands. So far as can be determined, all bundles lie within 2.5 mm. of the pith margin.

LEAF TRACES.—In figure 3 is shown the manner in which the primary strand divides near a node so the two bundles lie on the same radial plane one higher than the other. The lower turns out to the secondary wood sharply and is followed by the upper branch, which, so far as could be determined, holds this inner or adaxial position, and the two emerge through the secondary wood retaining this relative position. This manner of branching is observed in both sections and fractures and appears to be a regular nodal feature typical of both traces.

The vertical distance of disturbance in the secondary wood caused by the emission of a leaf trace bundle is about 6 mm. The trace therefore curves sharply and in the upper part of its course is almost horizontal in position. Because the distance between nodes is about 1.3 mm. and the traces pass through the secondary wood within a vertical distance of 6 mm., a transverse section of the stem will show five pairs of outgoing leaf traces, one or two of which will be obscure because they are in an early stage of emission. In figure 18 the traces are shown imperfectly, partly because of the transparent quality of the petrifaction. Their position has been marked in the figure as determined with a hand lens. The sequence as observed here, conforms with the arrangement shown in figure 1.

The four figures, 7, 8, 9, and 15, illustrate the changes which are typical of each bundle as it forms the anodic reparatory strand and diagonal kathodic bundle, then turns out to become a leaf trace. Figure 8 is a camera lucida drawing from a section cut about 5 mm. below a node at a point where the anodic and kathodic strands diverge and lie tangential to the main bundle. The smaller xylem elements are variously placed. In the anodic strand (shown at the left) the arrangement appears to be exarch, in the central strand endarch, and in the kathodic strand lateral in position. Secondary wood opposite the bundle is not organized into a column at this

level and apparently has no primary xylem at the inner margin. The general appearance of the spherulites is shown in this drawing and omitted from all others. Within the secondary wood zone a diagonal band of indistinct tissue is seen where the cells have broken down, a condition which is common locally in both primary and secondary wood.

Figure 7 was made from a cut at a higher level where the two branches have diverged widely and are not shown. The primary bundle is divided so the lower part is in contact with a column of secondary wood and is connected with the upper part (buried in the pith) by greatly elongated pith cells. The outer or largest branch appears to be endarch. Figure 9 shows a trace as it enters the wood column where the two groups of primary xylem elements are cut obliquely because they curve outward immediately upon entering the wood zone. Where a leaf trace enters the secondary wood, neighboring tracheids of the column are not at once carried out, but distally these lateral elements incline toward the primary xylem and farther out are caught up in the emerging bundle and carried out with it.

Figure 15 includes a trace buried in the secondary wood. Downward extensions of radially arranged secondary elements are shown closing the gap between the trace and pith. The primary elements being inclined at an angle are cut diagonally, which makes their arrangement obscure. There appears to be two groups of protoxylem surrounded by larger elements which are interpreted as being metaxylem. The arrangement is probably mesarch. The heavy border in the lower center marks the transition between secondary wood carried out on the abaxial side and the column beneath it which is not diverted.

The three figures, 4, 5, and 6, show the arrangement as seen in tangential sections cut near and beyond the point where the individual trace terminates in the secondary wood. Figure 4 is immediately proximal to the terminus. At this point there are two protoxylem groups vertically arranged and separated by metaxylem and some parenchyma. The bundle is mesarch. Rows of secondary elements completely surround the primary strand and have a loose arrangement due to the presence of wood rays. A prominent crescent of parenchyma overlies the bundle.

posed pith.  $\times$ 46.—Fig. 11. A small primary strand in a submarginal position, showing endarch arrangement.  $\times$ 50.—Fig. 12. Division of a primary bundle into inner and outer strands, immediately before turning out to the secondary wood to form a trace. Both bundles enter the leaf trace.  $\times$ 50.—Fig. 13. Division of a primary bundle to form a looped branch or ramification, composed of two elements which are apparently metaxylem.  $\times$ 50.—Fig. 14. A tangential section of secondary wood about 1 cm. from the pith. Rays are prevailingly high and wide. A few are uniseriate and low. Ray cells are typically higher than wide.  $\times$ 37.—Fig. 15. A transverse section of a leaf trace passing through the secondary wood zone. Note the narrow columns of secondary elements closing the gap behind the trace, the elongated pith cells, the protoxylem strands radially placed between the flanking columns of secondary wood, the presence of parenchyma in the trace, and the angle at which the trace is cut because of wide divergence from the vertical axis.  $\times$ 37.—Fig. 16. A tangential section of secondary wood within 1 mm. of the pith, where ray cells are dilated tangentially. The narrow secondary wood columns curve about the rays. Small uniseriate rays extend to the pith.  $\times$ 37.—Fig. 17. Radial section of secondary wood showing characteristic features of the pits and their arrangement.  $\times$ 220.

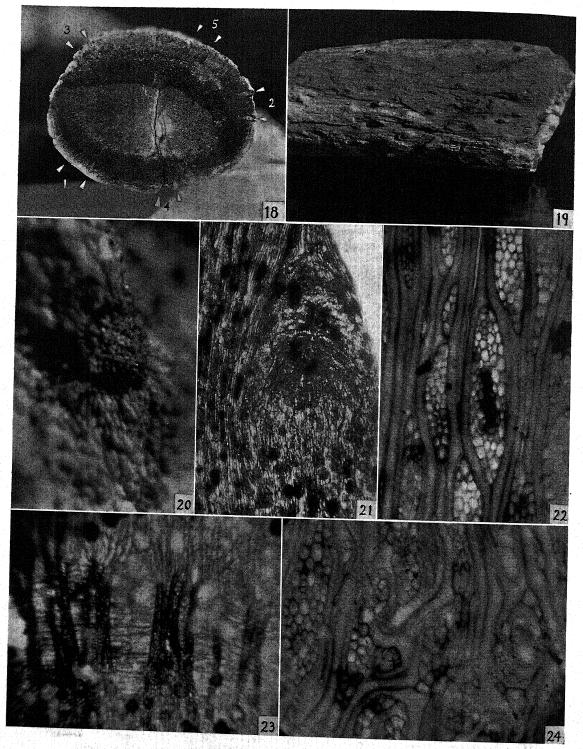

Fig. 18-24.—Fig. 18. A transverse section of the stem showing the large pith, narrow wood zone, and paired arrangement of traces. Traces which are obscure in the photograph are marked as determined with a hand lens.  $\times \frac{3}{4}$ .—Fig. 19. Side view of the stem showing the low protrusions due to convoluted tracheid masses which closed over the leaf traces.  $\times \frac{2}{3}$ .—Fig. 20. A sclerotic nest embedded in the pith, as seen on the surface of a fracture. In this instance the central mass of cells has not broken down.  $\times 50$ .—Fig. 21. An outgoing leaf trace cut near the terminus, showing the wide, short rays, abaxial to an outgoing leaf trace.  $\times 60$ .—Fig. 23. A transverse section of the pith margin and

Figure 5 was made from a section cut immediately off the terminus of a trace and shows a prominent mass of parenchyma which has the general outline of the bundle. Scattered tracheids occur in the mass which is probably callus tissue.

Figure 6 was made from a section cut about 1.5 mm. beyond a trace terminus and shows convoluted loops of tracheids which have closed in opposite the bundle terminus. The arrangement here resembles that found abaxial to the emerging trace in having numerous rays which are short, four or five cells in maximum width, and almost round. At two or three

places branched tracheids may be seen.

SECONDARY WOOD.—The zone of secondary wood has a maximum thickness of 13 mm. The preservation is such as to indicate that little of the secondary wood is lost. Apparently the stem when interrupted in growth was in its second growing season, since the leaf trace bundles are visible on all sides but are closed over and covered with about 2 mm. of wood in such a manner that the small protrusions

mark the points of emergence.

The wood is not dense like that of Cordaites and Eristophyton, but is characterized by broad wood rays (fig. 14, 16) such as are typical of Pitys (Scott, 1902) and Calamopitys (Scott and Jeffrey, 1914). Secondary tracheids are of medium size with an average tangential diameter of about 40  $\mu$  and a radial diameter of 44.5  $\mu$ . From two to six radial rows of tracheids lie between neighboring rays. The most frequent number is four. Where they meet the pith, rows of xylem elements are most frequently one or two cells wide and are not arranged in wedges or columns such as characterize Callixylon (Zalessky, 1909), except near or immediately below a node where a small column is formed partly by conjunction of neighboring xylem rows (fig. 23).

Pits are limited to the radial walls of secondary tracheids except immediately abaxial to outgoing traces where tangential pitting occurs sparingly. Pits are arranged in 1-3 vertical series, are uniformly distributed, and alternate in arrangement (fig. 17). Most of them are round and contiguous. Rarely in the larger elements they may be crowded and hexagonal. The pore is a narrow inclined slit, with the pit completely bordered. The characteristic features of pitting cannot be observed except locally in favorable areas. Throughout, most of the

stem pits are either obscure or invisible.

Wood rays vary from one to seven cells in width. The narrow and very wide rays are rare, while those of three or four cells in width are most common. Rays are high except near an outgoing leaf trace where they may be short or rounded (fig. 14, 16, 24). The maximum height observed is ninetytwo cells. Many are thirty to fifty cells high. No ray tracheids are visible, but occasional rays are composed of large cells or bordered by cells of unusual size such as have been described for Pycnoxylon (Cribbs, 1938), where they sometimes include tracheid elements. Where rays meet the pith, they are dilated, many of them in a striking manner (fig. 23). This is due to the tagential elongation of ray cells in that region. Farther out in the secondary wood ray cells are elongated radially and become muriform. Radial sections where they cut a dilated ray show the cells to be approximately square with the corners slightly rounded.

RELATIONSHIP.—This stem has a combination of structural features which make difficult its classification in relation to types previously described. This difficulty is increased because of the absence of cortex, leaf bases, and reproductive structures. The characters are a peculiar combination of those generally ascribed to genera of three groups-Cordai-

teae, Pityeae, and Calamopityeae.

The presence of a pith two inches or more in diameter, surrounded by a zone of secondary wood through which leaf trace bundles pass out to the cortex in pairs, diverging from the stem axis at a wide angle, are features characteristic of certain Cordaiteae (Scott, 1923). In contrast to these features many others of importance are indicative of relationship with the Pityeae. Among these are the following: wide wood rays, a large number of primary strands all of which are embedded in the pith near its margin, radial elongation of pith cells, wide dilation of rays near the pith, sparse pitting on tangential walls of tracheids abaxial to emerging traces, conspicuous distortion of tracheids in the neighborhood of outgoing traces, secondary tracheids surrounding the trace well out in the secondary wood, absence of rounded pits in the metaxylem of the primary bundle, and bundles of small size at the nodal position.

There are a few features which do not conform to the pityean plan. Of these the most important are: paired traces that originate from separate bundles, primary strands much reduced in the lower part of their course, an endarch tendency, reparatory strand lateral to the bundle, sclerotic nests in the pith, and subsidiary branches from the primary

bundles limited to the marginal zone.

Although sclerotic nests have not been reported for the Pityeae, this may not be significant, since they occur in different groups of paleozoic plants characterized by a large pith, including Lyginopteris (Kubart, 1914), Eristophyton (Scott, 1902),

and Mesopitys (Zalessky, 1911).

There is a resemblance to Eristophyton (Scott, 1902) in the presence of sclerotic nests, a continuous parenchymatous pith, and primary strands with metaxylem reduced in the lower part of their course. In other respects a comparison with this genus serves to emphasize the difference. Eristophyton differs in having primary strands in a marginal

secondary wood. Note the dilation of rays and ray cells, radial elongation of marginal pith, slender columns of secondary wood at the pith border, and the spherulites. ×20.—Fig. 24. Branched tracheids and rounded rays abaxial to an outgoing leaf trace. ×70.

position, bundles much enlarged at the nodes, metaxylem elements much larger than the secondary elements, metaxylem with many rows of rounded pits alternately grouped, leaf traces that originate and pass out through the wood singly, and rays that are

narrow or of the cordaitean type.

The double leaf trace which is typical of most cordaitean genera is also present in some of the Calamopityeae, including C. americana (Scott and Jeffrey, 1914), where it is formed by division of a single bundle at the node. The double trace arrangement of this stem resembles more closely that of Diichnia (Read, 1936), since each trace of the pair connects with a separate bundle at the inner edge of the secondary wood. It differs from Diichnia, in which two adjoining bundles give off leaf traces at each node, for in this stem the two which form traces at a node are regularly separated by two intervening bundles which may be either branched or simple. Diichnia has a 2/5 phyllotaxis, "mixed pith," mesarch primary bundles, and medium sized five angled pith, all of which are in contrast with corresponding structures of this stem.

There is a resemblance to both Calamopitys americana and Diichnia in having one of the traces of a pair slightly more apical or higher than the other, the difference varying from .5 mm. to 1 mm., in this stem, which is scarcely appreciable where the two traces have a tangential divergence of 1 cm. The wide high rays which have been compared with those of Pitys likewise resemble the rays of the more herbaceous Calamopitys species, except that in the latter there is less dilation near the pith.

There are occasional branched tracheids which lie abaxial to the outgoing trace and appear to be restricted to this region of excessive distortion. This feature has previously been reported for one species only—namely, Calamopitys eupunctata

(Thomas, 1935).

In regard to the geological horizon, this stem is somewhat later than the known Calamopitys species of semi-herbaceous habit, most of which have been reported from the Upper Devonian strata. It is approximately contemporaneous with Pitys and Eristophyton, reported from Scotland and Europe. Since it belongs to the lower part of the Mississippian, it preceded the great divergence of cordaitean forms of the Pennsylvanian. Whether or not it is too late to be in the line of descent between a Pteridosperm ancestor and the Cordaiteae is not in the writer's opinion a closed question, since it is not certain that all Dadoxylon types of secondary wood reported from the Devonian and Mississippian belong to the Cordaiteae. More evidence is needed regarding the primary structure, foliage, and reproductive parts of these early plants referred to Dadoxylon. It may well be true, that the Cordaiteae evolved from transitional types which flourished in the Mississippian.

The structural features of this plant are such that it may have been in the line which led eventually to the Bennettitales or Cycadales. Judging from the

meager evidence at hand, the stem was probably a stocky unbranched vertical axis, with densely clustered leaves of large size, the basal ones falling away as new ones developed above. Such is the general habit of the cycad with which a comparison reveals a certain degree of structural resemblance including a large pith, narrow wood zone, complex spiral, wide wood rays, and short internodes. The primary bundles which are greatly reduced in size may be considered as transitional between the more modern gymnosperms which lack them and the herbaceous type of Pteridosperm where they are prominently developed.

Because of the combination of structural characteristics this plant cannot at present be classified with certainty. Many important structural features indicate a place in the Pityeae, others of apparent equal importance indicate a place in the Pteridosperms, and whether it be included in one group or the other depends upon the relative weight given to the several primary structural features. In most respects the features which are not in agreement with the known Pityeae indicate affinity with the Calamopityeae rather than with the Cordaiteae. There is a possibility that further studies of the Reed Springs Flora will provide additional evidence through the discovery of closely allied plants.

Species and genus description.—Cauloxylon ambiguum, gen. et sp. n.—Pith very large (52 mm. wide), continuous, without ducts, with marginal zone of radially elongated cells, central zone with cells approximately isodiametric. Sclerotic nests abundant, limited to central pith zone, spherical, .4 mm. average diameter, surrounded by pith cells that radiate in all directions. Primary bundles distinctly separated, about 100 in number, all submarginal, much reduced at lower levels, about 16-20 cells at node, strong endarch tendency with protoxylem position variable in smaller bundles, anastomosis and branching common, subsidiary strands of 2-4 elements common and frequently radially grouped in relation to the primary bundle. Leaf traces paired; formed from separate bundles between which two others are intercalated; traces with two strands radially grouped; mesarch primary xylem; encircled by secondary elements distally; and about 200 -400  $\mu$  wide at the node. A reparatory strand and diagonal branch formed from each of the bundle pair, the former lies on the kathodic and the latter on the anodic side. Reparatory strands extend to 34th node above. The diagonal branches connect one with the 8th, and the other with the 13th node above. Phyllotaxis 20/34. Secondary xylem 13 mm. thick; tracheids 40 µ tangential  $\times$  44.5  $\mu$  radial diameter; rays wide and high, short and rounded adjacent to outgoing trace, widely dilated near the pith; certain rays entirely or in part of higher larger elements. Secondary tracheids adjacent to outgoing trace distorted and highly convoluted, occasionally branched or tangentially pitted. Pits of secondary wood uniformly distributed, alternate, 1-3-ranked, rounded and contiguous, rarely crowded and hexagonal. Pore an inclined slit, completely bordered. Metaxylem of trace with multiseriate pits, that of submarginal bundles about same size as secondary wood and transitional between reticulate and pitted.

#### SUMMARY

This stem is the third of a series to be described from the Reed Springs Formation of southwestern Missouri. It is a synthetic form combining characteristics of the Calamopityeae, Pityeae, and Cordaiteae. In most respects it resembles Pitys but differs sufficiently to justify separation from that genus. The points of difference for the most part indicate close affinity with the Calamopityeae. The stem fragment found was about 15 cm. long, 7.5 cm. wide, and 5.5 cm. thick. It has a phyllotaxis represented by the fraction 20/34. It is straight and without evidence of branches. It resembles Pitys in the following important respects: a very large pith, pith cells radially elongated, about 100 isolated primary bundles embedded in the pith near its margin, rays which are wide, high, and dilated near the pith, a limited amount of tangential pitting, metaxylem of small size and not fully pitted in the primary bundle, and outgoing traces completely surrounded by secondary tracheids distally.

The stem differs from Pitys and shows Calamopityean affinity in having many sclerotic nests in the pith, paired leaf traces which originate from separate bundles, leaf gaps with reparatory strand in an anodic position, reduction of metaxylem in the lower extension of bundle, and in the evidence of its having large leaves. Its definite placement in relation to the Pitveae or Calamopityeae is provisional, pending further studies of the Reed Springs

# OSMOTIC AND PERMEABILITY RELATIONS IN THE NUTRITION OF FUNGUS PARASITES 1

## F. S. Thatcher

THE SPECIALIZED relationship which exists between such highly evolved parasites as the rust fungi and their hosts has been the subject of voluminous comment, but the physiological mechanism

<sup>1</sup> Received for publication January 11, 1939. Contribution from the Faculty of Agriculture, McGill University, Macdonald College, Quebec, Canada. Journal Series No. 117.

This work was carried out during the tenure of a demonstratorship in the Department of Plant Pathology at Macdonald College, Faculty of Agriculture, McGill Uni-

Grateful acknowledgment is made of the assistance and guidance given throughout this work by Professor G. W. Scarth, Professor of Botany, McGill University, and of the timely suggestions and criticisms from Professor J. G. Coulson, Professor of Plant Pathology, Macdonald College, McGill University.

by which these fungi are able to obtain the necessary nutrients from the host cells, without causing any marked injury, has received little attention or explanation. The more destructive parasites which manifest the phenomenon of "action in advance" are considered to be able to satisfy their nutritional requirements from materials liberated from host cells which are killed by an enzyme or toxin secreted by, and diffusing in advance of, the encroaching mycelium; but the more highly specialized parasites such as the rust fungi employ no such drastic action.

Fundamental processes in the absorption of food materials by cells are those associated with osmotic pressure and permeability. Little direct investigation of these phenomena in connection with the feeding of parasitic fungi has been accomplished.

Steiner (1930) suggested that the osmotic value of urediniospores might offer a basis for differentiation of physiological forms of cereal rusts, but Hassebrauk (1932) later concluded that the method was inapplicable because of the many factors effective in modifying the osmotic value of spores.

Ronsdorf (1934) presents a value of 49.5 atmospheres for the osmotic pressure of urediniospores of *Puccinia triticina* and finds that urediniospore germ tubes of *P. simplex* have an osmotic pressure of 30.4 atmospheres while the value for cells of their host plant (barley) is only 9.5 atmospheres.

Rippel (1933) states that the rate of germination of spores of several fungi varies directly as the osmotic pressure of these spores. A Botrytis sp. parasitic upon Cladosporium fulvum had a much greater osmotic value than did the latter.

Hawkins and Harvey (1919) estimated the osmotic pressure of Pythium debaryanum to be 54 atmospheres. This pressure was found to be greater than the resistance to mechanical penetration possessed by cell walls of tubers of susceptible varieties but less than that of disease resistant varieties. Corner (1935) states that formation of haustoria by powdery mildews without piercing or killing the protoplasm of host cells indicates that the "turgor pressure in the penetration process is greater than that in the host cell." Pady (1935) makes a similar observation for rust fungi.

Graf-Marin (1934) states that spores of Erysiphe graminis will germinate at 90 per cent relative humidity and suggests that this indicates that these spores have a minimum suction pressure of 142 atmospheres. Yarwood (1936) later found that these spores would germinate in an atmosphere above C.P. sulphuric acid. Hence, it would seem that the minimum relative humidity for spore germination cannot always be considered as an index of osmotic pressure of spores.

Information bearing on the relative osmotic pressure of non-necrotic diseased tissue and of healthy tissue of plants infected by parasitic fungi is largely indecisive. In some instances conclusions have been drawn from observations of "plasmolysis" in fixed sections, which would seem to be of dubious accuracy. Tischler (1911) found that diseased tissue of pea plants attacked by Uromyces pisi had a higher osmotic pressure than healthy tissue. Allen (1923) states that when Mindum wheat is attacked by Puccinia graminis tritici, cells in the vicinity of the parasite are plasmolysed. The same writer (1926) reports that the hyphae of P. triticina induce an increased turgor in the adjacent cells of Little Club wheat. Dufrenoy (1928) states that cells of Arisaema triphyllum infected by Uromyces calladii became plasmolysed in an 8 per cent sucrose solution, while healthy cells of the same section remain turgid. Rice (1934), in studies on the same rust, finds no difference in degree of plasmolysis of diseased or healthy tissue at this or at higher concentrations. Hursh (1927) states that parasitism of wheat plants by Puccinia graminis effected no change in osmotic pressure as determined cryoscopically. Ruttle and Fraser (1927) found that oat plants invaded by *Puccinia coronata* show a heightened turgor among the cells immediately influenced by the rust's attack.

Attempts have been made to correlate varietal resistance to parasitic fungi with osmotic pressure of the host cells. Pantanelli (1921) and Johnson and Johnson (1934) in their studies on rusts of pea and wheat, respectively, reported a negative conclusion in each case. Shaw (1935) shows that resistance of apple trees to Bacillus amylovorus is correlated with the relative humidity in the intercellular spaces of host tissue as determined from the osmotic pressure of cells adjacent to the bacteria.

Measurements of permeability in relation to parasitism are few indeed. Fischer and Gäumann (1929), in a discussion of modified water relationships found in plants parasitized by rust fungi, suggest that alteration of permeability of the cell membrane, together with mechanical injury, bring about a disturbance of osmotic equilibrium which is responsible for the observed abnormalities. Link and Wilcox (1936) suggested that nutrients may be made more available to the fire blight bacillus (Bacillus amylovorus) by an increased permeability of host tissues caused by the parasitic activities of the organism. No measurements are presented. Thatcher (1935) demonstrated, by the plasmolytic method, that Uromyces fabae brought about an increase in permeability of the plasma-membrane of cells of its host (Pisum sativum) in the vicinity of the invading mycelium. Gretschushnikoff (1936) states that toxins elaborated by Puccinia coronifera cause increased permeability of leaf tissues of oat plants. The method of measurement was not stated in the abstract available.

The above observations are largely indirect and inconclusive. Accordingly, studies were made on the osmotic pressure and permeability relationships of various host-parasite associations with the hope of obtaining some information on the mechanism of nutrition, particularly of rusts.

MATERIALS AND METHODS.—In order to make comparison between organisms representing different degrees of specialization in their mode of parasitism, the fungi used in these studies were selected from two conventional groups—namely, (1) obligate parasites and (2) parasites which kill the cells of their hosts in advance of their mycelium. The species selected from these groups were, respectively, (1) Uromyces fabae (Pers.) de Bary, causing the rust of garden pea (Pisum sativum), and U. caryophyllinus (Schr.) Wint. on carnation (Dianthus caryophyllinus); (2) Sclerotinia sclerotiorum (Lib.) Mass. and Botrytis cinerea Pers. on celery (Apium graveolens). By means of plasmolytic methods the osmotic pressure of the respective hosts and parasites was compared, and the influence of the various fungi on the permeability and osmotic pressure of the host cells was determined by comparing these properties at different distances

from invading hyphae. The precise technique had to be modified according to the materials used, as reported below.

Osmotic pressure determination.—For ease of observation, all preparations were vitally stained with neutral red, 200 p.p.m. in tap water. Calcium chloride was always used as plasmolyte, the solutions

being made up from anhydrous CaCl<sub>2</sub>.

The osmotic pressures of urediniospore germ tubes were determined by the method of Ronsdorf (1934) who considered as isotonic with the germ tubes of Puccinia triticina the strongest solution in which the spores would just germinate. Urediniospores of Uromyces fabae were floated on calcium chloride solutions contained in Van Tieghem cells which were kept in moist chambers. Germination was estimated after 18 hours. The solution considered isotonic with the spores was the one in which initial germ tube protuberances were visible to the extent of 50 per cent of the proportion of germ tubes which would develop in tap water.

The osmotic pressures of haustoria of Uromyces fabae and of U. caryophyllinus, and of hyphae of Botrytis cinerea and Sclerotinia sclerotiorum, were determined by the plasmolytic method. Incipient plasmolysis of haustoria could be observed directly in sections of infected tissue placed in the appropriate concentration of calcium chloride. Some difficulty arose in ascertaining the osmotic value of hyphae of Botrytis and Sclerotinia because of the great inequality in proportion of vacuolar space in different hyphae and because partial collapse of the hyphal wall was sometimes brought about by hypertonic solutions.

The isotonic value of very elongate hyphal cells with relatively large vacuoles - which generally showed a "convex" type of plasmolysis-was arrived at by first measuring the lengths of a number of successive vacuoles in a particular filament, while mounted in water. These same vacuoles were watched carefully during irrigation with progressively stronger solutions of salt until shrinkage (plasmolysis) of the vacuoles began. The hyphae were then more strongly plasmolysed and after equilibrium had been attained were further irrigated with progressively weaker solutions until the original sum of vacuole lengths was reached. The average between the respective mean concentrations at which shrinkage first appeared and at which the original length was regained was considered as isotonic with the fungus filament.

Those hyphae which were rich in protoplasm and in which the many minute vacuoles could not be measured, commonly plasmolysed in a "concave" fashion—i.e., the protoplasm receded from the walls at irregular intervals. With such hyphae, the isotonic solution was regarded as the one in which all these concave identations had just disappeared during deplasmolysis.

Camera-lucida drawings of hyphae plasmolysed in concave and convex manner are shown in figures 1B and 2, respectively.

Osmotic pressure of the host cells.—The osmotic pressure of host cells was determined in all cases by the incipient plasmolysis test. Thin free-hand sections were immersed in calcium chloride solutions of different concentrations and the number of cells showing some degree of plasmolysis and the number not plasmolysed, in fields totaling at least 100 cells, were determined after 30 minutes. The percentage number of cells showing plasmolysis in each concentration was then plotted against concentration, and the concentration at which 50 per cent of the cells were plasmolysed (the isotonic value) was determined from this graph.

In addition to the above method, the osmotic pressure of infected and non-infected tissues from rusted pea plants was also obtained by Höfler's (1931) "plasmometric" method. For cells of cylindrical shape, a closely approximating value for the degree of plasmolysis brought about by a hypertonic solution is indicated by the expression [l-d/3]/h, where l = length of plasmolysed protoplast, d = width of plasmolysed protoplast, and h = original length of protoplast before plasmolysis. The product of this quotient and the concentration of the plasmolysing solutions gives the isotonic value of the cell sap before plasmolysis (see Scarth and Lloyd, 1931).

Permeability determinations.—Comparative values of permeability of host cells in tissues invaded by fungal hyphae and of cells well removed from the infected zone were obtained with respect to water, urea, thio-urea, and dextrose. These substances form a series of increasing molecular size and decreasing rate of penetration and are therefore useful in estimating the pore size of the plasmamembrane. They are also substances of a type similar to those which may serve as food for the fungus and which, in whole or part, occur in the host cells. The presence of urea is problematical. The existence of urease in cells is regarded as indicating the speedy breakdown of any urea which may be formed, and, indeed, urea could hardly be expected to accumulate because of its ready passage through the protoplasm. However, changes in urea permeability are no doubt indicative of similar changes toward other highly diffusible nitrogenous compounds. The principal object of the investigation was to find out if any degree of permeability is developed toward nutrient solutes which the host cells contain in quantity and to which healthy cells are "passively" semi-permeable. Dextrose was selected as representative of this class of substance.

The cells compared were from the same organ and the same zone of tissue. The relative permeability of similar cells in the respective regions is all that is required for the present investigation, but the absolute or "protoplasmic" permeability—that is, the permeability per unit area of protoplast—has also been calculated. This latter value is particularly useful since it permits universal comparison of permeabilities of cells from different tissues and

species, irrespective of the dimensions of the cells considered.

Calculations of passive permeability as measured by the plasmolytic method are based on the change in the volume of a protoplast occurring in a known time due to diffusion between the vacuolar solution and the external solution. This is most conveniently arrived at by measuring the increase in volume during deplasmolysis of a protoplast which has previously been plasmolysed.

Where the test substance is a solute, any increase in volume which occurs while the cell is immersed in a hypertonic solution is due to the fact that penetration of the solute increases the amount of osmotically active substance within the cell so that water is drawn into the cell. The volume change depends on the amount of solute entering.

If water is the test substance, volume change is measured while water diffuses from a hypotonic solution of known strength. The volume change may be obtained either by linear measurement with the aid of an ocular micrometer or by estimation after the cell has been plasmolysed initially to a known degree.

The time taken for deplasmolysis of cells of similar dimensions after they have been plasmolysed to the same degree gives a measure of relative permeability. Absolute permeability may be calculated from consideration of volume change within a given time under conditions of known osmotic pressure

difference. As is indicated by Scarth (1939), the rate of volume change at any moment, dv/dt, is expressed by the following general formula: dv/dt = p.c.s., where p = the coefficient of permeability of the protoplasm, c = the difference between the effective concentrations inside and outside of the protoplast, s = surface area of the protoplast.

Scarth shows that with proper precautions p in the above formula can be kept practically constant throughout deplasmolysis and that the variables c and s can often be expressed in terms of v—a condition which is necessary for the solution of the equation.

An obstacle inherent in calculation of permeability is the difficulty of estimating s and v, which is only possible when the shapes of the cells tend to a definite geometrical form.

Scarth expands the above equation and derives formulae comprised only of easily measurable factors, applicable to cells approaching cylindrical, cylindro-prismatic, and spherical form. By ingenious substitutions, Scarth has reduced these formulae to simple expressions which in some instances curtail the measurements necessary and which give results well within the limits of experimental error unless applied to cells having a low ratio of length to breadth. The formulae can be made rigorous by reference to a table of corrections presented in Scarth's paper (1939).

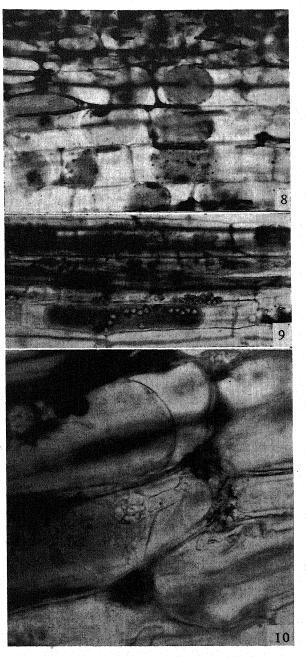

Fig. 8-10.—Fig. 8. Cells of the type commonly used for determination of permeability by the plasmolytic method.
—Fig. 9. The type of cell chosen for determination of permeability by the plasmometric method. Note the high proportion of length to diameter.—Fig. 10. Plasmolysis of an infected host cell without plasmolysis of the haustorium, indicating the superior osmotic value of the haustorium.

The sections were cut thin, so that, for the most part, they were only one cell thick. As a consequence, no blanketing effect on diffusion rate was manifest even in cells situated in the middle of a section. Table 1 shows that, on the average, the latter deplasmolysed at exactly the same rate as cells at the edge. This means that available surface (s in the primary equation) is the whole surface of each cell. The table also shows the degree of individual variation among the cells. This is considerable when cells are rapidly deplasmolysed in hypotonic solutions, as used in measuring water permeability, but is slight in gradual deplasmolysis as in hypotonic urea solution. Probably the variability shown in the former represents not so much normal variation of permeability as abnormal variation caused by rapid stretching of the plasma membrane, since always a certain number of the cells showed injury in deplasmolysis. To equalize this mechanical effect as much as possible, the sections compared were brought to the same degree of plasmolysis, as is described later.

In shape all the cells studied were more or less cylindrical. Those selected for the most important tests were about five times as long as broad. The bulk of the tissue in all preparations, however, was made up of cells only from three to four times as long as broad, and it was with such cells as well as with the narrower ones that most of the tests were made. The results presented have been calculated from Scarth's simplified formulae using the correction indicated in Scarth's table.

Details of the experimental procedure are as follows:

Water permeability.—The osmotic value (O) of the cells having been determined, the cells were plasmolysed for 20-30 minutes in CaCl<sub>2</sub> of conc. 2 O. They were then transferred to a solution of conc.  $\frac{1}{2}O$ , and the time (t) required for completion of deplasmolysis of 50 per cent of the cells was noted. The average diameter of the cells (d) was also determined. P (absolute permeability) = d/5 t O (Scarth, 1939).

Urea permeability.—In using the plasmolytic method for measuring solute permeability, the osmotic value of the cells was first determined, as described before. The sections were then transferred to a solution of penetrant of concentration 2 O. (As

plasmolysis was smooth and convex, this procedure is free from the objections that apply when there is much adhesion to the wall.) The time for completion of deplasmolysis was noted and the average diameter (d) of the cells determined. In this case absolute permeability to solute (Ps) is given by the formula Ps = d/4t.

Permeability to dextrose—plasmometric method. In a solution such as that of dextrose which normally penetrates cells very slowly or not at all. complete deplasmolysis, if ever it occurs, is likely to be preceded by changes in the osmotic pressure and permeability of the cells. The plasmometric method gives results in a small fraction of the time required by the plasmolytic. In using this method, the cells were plasmolysed in a dextrose solution, and after equilibrium was reached the length of the protoplast (lmin.) was measured. After a suitable time the length of the same protoplast was again measured (1). In experiments in which it was desired to estimate the average permeability of a number of cells which could not always be recognized individually with certainty, the average length l was corrected in proportion to the ratio of L (average) in the second set to L in the first set of measurements. L being the length of the entire cell.

In this case  $Ps = [(l-l_{\min}) d]/4 t l_{\min}$ 

RESULTS.—Osmotic pressure.—Host v. parasite.

—The osmotic pressure of each of the parasites investigated was found to be considerably greater than that of its host, as seen in table 2. MacDougall (1911) and Harris (1916) have stated that such a relationship is general between angiospermous parasites and their hosts.

The value obtained for germinating urediniospores of *U. fabae* (vide table 2) is in close agreement with the value presented by Ronsdorf (1934) for *Puccinia triticina*: *U. fabae* 43.5-45 atmospheres, *P. triticina* 43.9 atmospheres. The method of estimation, however, is indirect, and it is not unlikely that these values, which are high for plant cells, may be accounted for partly by an adaptation of the spores to the abnormally high osmotic pres-

Table 2. Osmotic pressure of parasite and host.

sure of their environment during the relatively long period of immersion in the test solutions (cf. Walter, 1934).

The average osmotic pressure of haustoria of Uromyces fabae and U. caryophyllinus was found to be 21.9 and 18.6 atmospheres, respectively. The relatively high osmotic pressure of haustoria of U. fabae, as compared with that of host cells, is subtantiated by figure 10, which shows a host-cell strongly plasmolysed without any plasmolysis of the haustorium being apparent. Evidence that the shrinkage of the protoplast observed in haustoria after immersion in hypertonic solutions was true plasmolysis and not an artifact is afforded by the camera-lucida drawings in figure 3. These drawings show the same haustorium, with vacuoles stained by neutral-red, at increasingly hypertonic concentrations of calcium chloride. The progressive contraction of the vacuoles is readily apparent. Cameralucida drawings of haustoria adjudged to be in the condition of incipient plasmolysis are shown in figure 7.

Infected vs. non-infected tissue.—Analysis of more than 300 measurements of cells from tissues interspersed with hyphae of *U. fabae* and from non-infected tissues of the same organ indicates a significant decrease of more than two atmospheres in the osmotic pressure of infected cells as compared

Table 3. Average osmotic pressures of infected and noninfected tissues of Pisum sativum (compiled from more than 300 measurements).

with non-infected cells. Summaries of these measurements are presented in table 3.

Permeability.—Permeability to water.—Marked increase in water permeability in tissues infected with U. fabae is indicated in table 4. In petioles, the rate of penetration of water into cells of infected tissues was more than five times as fast as in healthy regions of the same organ. In leaf tissue (palisade cells) almost a threefold increase was noted. Sudden disruption of the cytoplasm in cells of infected leaf tissues occurred frequently during deplasmolysis. This probably indicates that the reported measurements are those of cells least modified by the presence of the rust hyphae.

In an attempt to determine whether or not this increase in permeability was brought about by a secretion from the fungus, sections of non-infected pea tissue were immersed in extracts from equal weights of leaf tissue, (1) from regions densely packed with hyphae of *U. fabae* and (2) from non-infected areas of the same leaves. Permeability measurements of these immersed tissues made at the conclusion of the period of immersion indicate that the permeability of the cells to water was increased much more by the extract from infected tissue than by the extract from healthy tissue (see table 5).

Examination of celery tissues attacked by Sclerotinia and Botrytis reveals the fact that each fungus causes an increase in permeability, a gradient in change being noticed from tissue in the immediate vicinity of the fungus to healthy tissue some distance away from the infection center (table 6). This change precedes death of the cells.

Permeability to urea and thio-urea.—Substantial increase in permeability of cells in infected tissues to urea and thio-urea as a result of parasitism by U. fabae and U. caryophyllinus is indicated in table 4. A graphical expression of the increase in permeability to urea by carnation leaf-base cells infected with U. caryophyllinus is given in figure 11. The curves were obtained by expressing rate of deplasmolysis in a strongly hypertonic solution in terms of the percentage of cells having completed

host cell membrane is modified in such a way as to permit dextrose to diffuse through it in measurable quantity, the permeability rate in this instance averaging about 0.00020 millimols pere square centimeter per hour per mol concentration difference.

Discussion.—Considering first the above measurements relative to rusts, the facts brought to light by the study of osmotic pressure and permeability suggest an explanation of how the rust fungi *Uromyces fabae* and *U. caryophyllinus* are able to obtain nutrients from the cells of their hosts without killing these cells.

As regards water absorption, the determining factor is of course suction pressure. Although this is not identical with osmotic pressure, yet in the relationship between parasite and host cell the maximum suction pressure which each of the two competitive organisms could exert would be equivalent to its respective osmotic pressure. Also, with equal turgor pressure, suction pressure varies directly with osmotic pressure. Hence, with its higher osmotic pressure, the fungus is able to remove water from neighboring parenchyma cells and can even maintain a certain degree of turgor in contact with non-turgid host cells or with their free sap.

As regards the absorption of foodstuff by the parasite from the cells of its host, the passive permeability of the latter would seem to be all important. We have seen that in all cases the fungus brings about an increase in permeability of the host cells, which is probably due to some sort of secretion, as indicated by the increase in permeability brought about by juice expressed from infected tissue. This increased permeability as measured by deplasmolysis extends even to dextrose so that probably some of the vacuolar solutes which are normally prevented from escaping become available to the fungus. In a non-turgid cell those components of the vacuolar solution to which the membrane has become permeable would diffuse out into the free water in the cell walls till its concentration there reached that in the sap. The amount would be relatively small. In turgid cells, however, in consequence of the reduction in osmotic pressure, water also will be forced out by wall tension. This mass outward flow of water and vacuolar solutes will also be checked when the reduced wall tension again balances the effective osmotic pressure so that cells do not lose turgor completely and remain alive.

The hypothesis that even an obligate parasite causes certain substances to leach from the host cells in its vicinity is supported by the fact that there is a reduced osmotic value in the tissues of Pisum which adjoin the rust hyphae. A reduction in osmotic value as tested by plasmolytic methods signifies a reduction of osmotically active solutes and is independent of changes in water content.

It is not intended to be inferred from the above discussion that change in permeability is the only physiological modification of the host cell essential for rust nutrition. Neither is it suggested that dextrose is the carbon source utilized by the rust fungi. It is certain, however, that whatever the compound used by the rust fungi, it must be one to which the host cell loses its semi-permeability, since the protoplasts of hosts and fungus are always distinctly separate. Dextrose is considered here only because it is representative of the type of diffusible carbon compound known to occur within cells.

The above hypothesis also sheds some light on a number of questions relative to the rusts for which no satisfactory explanations have been offered.

Several workers, including Smith (1900), Rice (1927), and Pady (1935), have shown that certain haustoria-producing parasites can develop an extensive amount of mycelium before forming haustoria, the development being far more than is possible by use of only reserve food contained in the spore. Arthur (1929) points out, also, that certain systemic rusts, in keeping pace with the development of the host, mingle with the meristem tissue, but do not form haustoria until cells at the growing point have become vacuolate. Such instances indicate that these fungi may obtain adequate nutrients to support rapid growth without use of specialized absorbing organs.

Each author asks by what means do these fungi procure their nourishment. The above explanation presents an answer. It may be extended to haustorial absorption if the common view is correct that the typical haustorium causes an invagination of the protoplasmic layers of the host cell and is not directly in contact with the vacuolar sap. Its function would then be to offer increased absorbing surface and to occupy a position favorable for immediate up-take of any material which "leaches" from the vacuole as a result of the membrane-modifying activities of the fungus.

Another phenomenon which may be interpreted in the light of the above is the commonly observed fact that a rust fungus develops best when environmental conditions favor maintenance of a state of high turgor in the tissues of its host. As already described, the rate of flow of vacuolar solution from infected protoplasts would be in direct proportion

to the turgor of the host cell.

Referring now to the destructive parasites Botrytis and Sclerotinia, the results presented in tables 2 and 6 indicate in each case that (1) the osmotic pressure of the fungus is greater than that of its host and that (2) permeability of the host plasmamembranes is increased. Thus, in the tissues as yet unaffected by their characteristic pectinase digestion, these organisms show the same type of influence as do the obligate parasites. The ability of these fungi to satisfy their water and food requirements during the initial period before pectic hydrolysis has reached completion, may perhaps be explained by the same hypothesis, since, in the case of celery tissue, at least, a decided increase in permeability is noted some distance away from killed cells. In addition, these permeability changes may well be influential in contributing to the total food supply after actual invasion of the tissues.

The difference in the relative pathogenicity of the two groups may be partly due to an adaptation whereby the rust fungus, in evolving a more specialized form of parasitism, has reduced the intensity of the factor through which the permeability of the host cells is increased and which, in the case of the "grosser" parasites, brings about an ultimately fatal modification. The view that a nonlethal action is to the advantage of the rust organism in maintaining continuance of its food sup-

ply is familiar.

#### SUMMARY

The osmotic pressure and permeability relationships between a number of parasitic fungi and their hosts were studied by plasmolytic methods.

The fungi used were Uromyces fabae on Pisum sativum, U. caryophyllinus on Dianthus caryophyllus, Botrytis cinerea and Sclerotinia sclerotiorum isolated from decaying celery petioles (Apium graveolens). Osmotic values were obtained for urediniospore germ tubes and haustoria of the rusts, for hyphae of Botrytis and Sclerotinia, and for diseased and healthy tissues of the various host plants. In all cases the osmotic pressure of the fungus was greater than that of its host.

Permeability measurements of diseased and healthy tissues in rusted plants indicate that the rust increases the permeability of the plasma-membrane of the host cells. Values for absolute permeability to water, urea, and dextrose were calculated by the use of the simplified formulae devised by Scarth (1939). This increase appears to be due to some secretion from the rust fungus as indicated by the increase in permeability brought about when healthy tissues are immersed in a juice-extract from tissues interspersed with rust hyphae.

An increase in permeability is also apparent in celery tissue some distance from the region of cells

killed by Botrytis or Sclerotinia.

Based on the above measurements, a hypothesis is elaborated to explain the mechanism for transfer of food and water from the host cells to those of the parasite as manifest in the above rusts. This hypothesis permits an explanation of how host cells are able to remain alive even though being continually taxed by the parasite, and it throws light on other hitherto unexplained phenomena.

# TWO NEW GENERA OF OPERCULATE CHYTRIDS 1

### Helen Berdan

In June, 1938, several saprophytic chytrids were noticed in a small piece of dead grass found in a collection of algae made in a pasture near Chapel Hill, North Carolina. Subsequent examination of fresh, boiled grass added to this showed the presence of seven chytrid species. Two of these were identified as Nowakowskiella elegans (Now.) Schröter and Cladochytrium replicatum Karling. Another was a small "dentigerate" form, and a fourth appeared to be a large, hyaline Cladochytrium species with exceptionally long exit tubes. The remaining three seemed sufficiently unusual in character to merit isolation from the confusing entanglement of the combined seven rhizoidal systems present in the grass tissue. To those familiar with the chytrids, such a separation may present no difficulties. To others, who, like the writer, are initiates in this field, the purely practical procedure may be both interesting and instructive.

The conditions of culture and study have been kept as nearly sterile as possible. All instruments, slides and cover glasses are flamed, all Petri dishes dry sterilized, all cultures maintained in sterile charcoal water made as described by Shanor (1937), on boiled substrata, and all washings done with distilled water. This and the purification methods described below were the procedures in the Chapel Hill laboratory where these cultures were begun (Couch, 1939). Two labor-saving innovations have been added. The laboratory at the University of Western Ontario is equipped with an air line from a compressor. Rubber tubing attached to the spigot conducts the air through a solution of HgCl2, then into the wash bottle. The continuous stream of water washes off rotifers, etc., with greater despatch and thoroughness than the ordinary wash bottle. We find that, with one careful washing, cultures may be kept in a cool room for several weeks in clean condition. Secondly, the leaves are boiled, then heated gently in 95 per cent alcohol in a water bath to remove the chlorophyll. These are stored on ice in stoppered flasks containing clean alcohol, which is then boiled out directly before using. Observations are made more easily in leaves treated in this way and chances of contamination reduced to a minimum.

The original culture was kept by the addition of new pieces of sterile leaves, a wise precaution, since during attempts at purification the chytrid may be lost. "Gross cultures" were obtained by washing pieces of infected leaves removed from the original dish, transferring them to sterile Petri dishes con-

<sup>1</sup> Received for publication March 10, 1939.

The writer is very grateful to Dr. J. S. Karling under whose direction this work has been carried on since September, 1938, to Dr. J. N. Couch for help with collecting and laboratory procedure, and to Reginald Haskins and Duncan McLarty for technical assistance.

taining sterile charcoal water, and adding fresh sterile pieces of leaf.

From gross cultures, a culture in which one chytrid predominates (the "accumulation culture") may be derived. When one has sufficient skill to isolate a single spore or sporangium from the gross culture, this intermediate stage may be discarded. However, while the experimentation necessary to achieve an accumulation culture is sometimes tedious, the process is effective in familiarizing one with the growth habits and morphology of each chytrid in the gross culture. It affords opportunity for a comparative study of these on a range of substrata and under a variety of conditions. It also increases the chances of observing heterothallism, which may not be noticed if a single strain is established too soon.

In the present case it was decided to discard the "dentigerate" form, Nowakowskiella elegans (Now.) Schröter, and Cladochytrium replicatum Karling deliberately and to acquire accumulation cultures of the other four if possible. The general

lines of procedure are described below.

1. Portions of leaves containing the "dentigerate" form were cut off and discarded. Since it was present in small quantities only, it was soon removed from the gross cultures and made no reappearance.

2. Nowakowskiella grew very quickly in the hot climate and completed its cycle more rapidly than the others in the gross cultures. When washings were made less frequently, it tended to die out of the cultures, and after a few weeks' time it was completely eliminated. (We have found that an accumulation of this chytrid may be obtained by pulling off rhizomycelium which is growing out into the water from the substratum and placing it on fresh substratum (Haskins, 1939).

3. The large Cladochytrium species with very long exit tubes grew very slowly. It seemed to thrive only in leaves of a certain grass found in Chapel Hill. It succumbed to the exigencies of travel from North Carolina, via New York, to London, Canada, over a period of three weeks in September, 1938. All the other chytrids survived this change easily. During travel they were carried in charcoal water in stoppered sterile test tubes and changed to sterile Petri dishes directly upon arrival in each place.

4. Cladochytrium replicatum Karling was most persistent. In spite of the fact that leaves containing it were discarded at once, it was very hard to eradicate from all cultures. It did, however, produce resting spores very easily, and when this happened while other chytrids were still producing active zoospores, the spores were washed off into fresh dishes, and gross cultures lacking C. replicatum were eventually established.

5. The fifth chytrid (an inoperculate form belonging to the Cladochytriaceae and called simply No. 5

in our laboratory up to date), Catenochytridium nov. gen., and Septochytrium nov. gen. (both described below) were got into the accumulation stage by varying the substrata as follows:

(a) Young wheat leaves were introduced into the mixed cultures of these growing in grass in August. The zoospores of Catenochytridium are comparatively sluggish in disposition and range of dispersal. When the wheat was added just as these zoospores were discharging, they settled upon it in great numbers, and infection occurred quickly. These leaves were at once removed, washed, and transferred to fresh dishes.

(b) Old, tough pieces of corn leaf were added to the mixed cultures in August. Septochytrium nov. gen. was able to maintain itself in these, especially near the veins, over a longer period than the others. These tough midribs with sporangia of Septochytrium were removed, washed, and transferred to fresh dishes to give the accumulation cultures.

(c) In February, 1939, leaves of rye were added to mixed cultures in which No. 5 had been growing weakly all winter. These became heavily infected, and sub-cultures showed no other chytrid present. Since then it has also been grown successfully on corn leaves.

By completely selective accumulation, by plating, or by the dilution method there is next produced a culture with only one chytrid species present. The term "unifungal," while clumsy, has been adopted for this type of culture with similar connotation to the "Art Reinkultur" of Kufferath (1929) or the "unialgal" culture of Smith (1933), Bold (1936), and others—viz., a culture containing only a single-

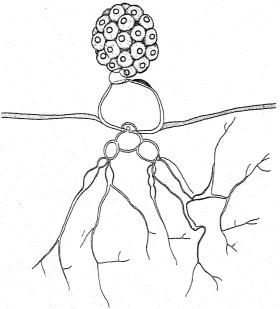

Fig. 1. Mature thallus of Catenochytridium carolinianum. The catenulate compound apophysis and the rhizoids are inside a cell of wheat leaf; the operculate sporangium with its attached spore case and the spore ball are extramatrical. Drawing made with Spencer camera lucida.

species of fungus (in this case a chytrid) although other organisms may occur. "Pure culture" might then be restricted to one consisting of only a single fungus species with no bacteria, rotifers, or other organisms present. This is the German "Absolut Reinkultur." Accustomed as we are to this in the higher fungi, there is but one record in the literature of members of the Chytridiales growing in "pure culture" for longer than a month (Couch, 1939). Sparrow (1931) obtained growth of Cladochytrium Nowakowskii on corn meal agar but not in pure culture. Butler and Humphries (1932) were successful in culturing Catenaria anguillulae, while Karling (1935) grew Cladochytrium replicatum on corn meal agar and soil mannite agar for a month before it became contaminated. Professor J. N. Couch, of the University of North Carolina, has made a "pure culture" of this last mentioned chytrid. It was secured during the summer of 1938 from an agar plate, on which a mixture of several of the chytrids from the original culture were growing, by the separation of rhizomycelium with sporangia and is, I believe, still being carried in his laboratory. He also records a form designated "Catenaria-like without rhizoids" as being in pure culture from a single spore since 1932. Four species of monocentric chytrids were carried on agar in pure culture for several generations from a single spore. The cultures were then discontinued because the "labor involved" was "excessive."

For morphologic descriptions unifungal cultures are satisfactory, and the writer has made no attempt as yet to procure "pure cultures" from them. Cladochytrium replicatum Karling, the large Cladochytrium species mentioned above, and one of the new genera (Septochytrium) have been grown on agar. Spores of the last two have been germinated on agar.

In November, 1938, several "accumulation cultures" of Catenochytridium nov. gen. seemed to be free from all other fungi. A piece of wheat leaf, taken from one of these, was separated under the binocular microscope into minute pieces containing one to several sporangia. Cultures made from these have contained only Catenochytridium nov. gen. since that time (a period of eight months). The genus is described below from this material. In August, 1938, a single spore was isolated on agar No. 12 (Leitner's agar) from an "accumulation culture" of Septochytrium nov. gen. using the method described by Couch (1939). The generic analysis is made from cultures of this single spore strain.

Catenochytridium nov. gen. (text fig. 1) is distinguished mainly by its catenulate, compound apophysis and endo-exogenous method of development, features which have proved constant; hence its generic name.

Catenochytridium gen. nov. Thallo intramatricali atque extramatricali, monocentrico, eucarpico. Zoosporangio extramatricali, operculato, pariete maturitate disjuncto. Zoosporangio evolvente endo-exogeno. Apophyside intramatricali, composita, seriebus linearibus facta segmentorum constrictorum atque catenulatorum subministrante rhizoideo systemate maxime ramoso. Zoosporis cilio pos-

teriore praeditis, cumulo globoso emergentibus quieteque aliquamdiu manentibus mox rapide atque emicatim enatantibus. Spora perdurante extramatricali, eodem loco quo zoosporangium formata, segmento apophysidis interdum in sporam perdurantem transformato; germinatione incomperta.

Catenochytridium carolinianum sp. nov. Fungus saprophyticus; zoosporangiis hyalinis, globosis, subglobosis, pyriformibus, obovatis, ovatis, ellipticis, reniformibus vel convolutis cum lobis apiculatis, 8-40  $\times$  8-75  $\mu$ . Operculo in vacuo sporangio cardinato atque persistente in loco apiculato vel subapiculato; orificio circulari, 6-20 μ dia. Apophysidis segmentis catenulatis numero 2-30, seriebus linearibus 1-4 primariae cellulae apophysidis adhaerentibus; primaria cellula apophysidis plerumque vel globosa vel ovata, 5.5-22 μ; ceteris apophysidis segmentis globosis, ovatis, ellipticis vel variatim elongatis, protoplasmatis nexu per parietem vel isthmo elongato conjunctis. Rhizoideo systemate (apophyside addita) 55-800  $\mu$  magnitudine; rhizoidibus .5-3  $\mu$  dia., minutissime ramificatis atque aliqua ex parte dichotomis. Zoosporis hvalinis, globosis, 5-6 μ, uninucleatis, cum uno globulo maxime refractivo c. 2.5  $\mu$  dia.; cilio 35-40  $\mu$  long. Zoosporis inficientibus plerumque cum pariete hospitis a latere conjunctis. Vetula capsa zoosporae plerumque in sporangio vel in spora perdurante persistente, depressa, hyalina vel sucinea-colorata crassaque, c. 8 µ dia. Cellulosa reactione in apophyside conspicua atque in capsa vetula sporae, parum conspicua in sporangii pariete, in rhizoidibus vix discernenda. Spora perdurante levi, globosa vel ovata, 8-40 μ, crassa, pallida vel atra-sucinea colorata, cum uno globulo permaximo atque strato parietali globorum minorum; germinatione incomperta.

Catenochytridium gen. nov. Thallus intra and extramatrical, monocentric, eucarpic. Zoosporangium extramatrical, operculate, delimited by a cross wall at maturity. Method of growth and development endo-exogenous. Apophysis intramatrical, compound, consisting of linear series of constricted, catenulate segments subtended by an extensive, richly branched rhizoidal system. Zoospores posteriorly uniciliate, emerging in a globular mass and lying quiescent for a few moments before swimming away; method of swimming rapid and darting. Resting spore extramatrical, usually formed in the same position as the zoosporangium or a segment of apophysis sometimes encysting and becoming a resting spore; germination unknown.

Catenochytridium carolinianum sp. nov. Zoosporangia hyaline, spherical, sub-spherical, pyriform, obovoid, ovoid, elliptical, kidney-shaped or convoluted with pointed lobes,  $8-40 \times 8-75 \,\mu$ . Operculum apical to sub-apical in position, hinged to and persistent on the empty sporangium; orifice circular, 6-20 μ in dia. Catenulate segments of apophysis 2-30 in number, arranged in 1-4 linear series attached to the primary apophysate cell; primary apophysate cell commonly spherical to ovoid,  $5.5-22 \mu$ ; other segments of apophysis spherical, ovoid, elliptical or irregularly elongate, joined by an imperceptible or an elongated isthmus. Rhizoidal system (including apophysis) 55-800  $\mu$  in extent; rhizoids from .5-3  $\mu$  in diameter, becoming very finely branched; branching somewhat dichotomous. Zoospores hyaline, spherical, 5-6  $\mu$ , uninucleate, with a single highly refractive globule about 2.5  $\mu$  in dia.; cilium 35-40  $\mu$  in length. Infecting zoospores commonly attached laterally to wall of host cell. Old zoospores case usually persistent on the zoosporangium or resting spore, slightly flattened, hyaline or amber and thick-walled, about  $8 \mu$  in diameter. Treatment with chlor-iodide of zinc producing a pale

mauve color in the sporangium wall, a deep mauve in the old spore case, a deep pinkish-mauve in the segments of the apophysis, magenta in the primary apophysate cell, barely affecting the rhizoids. Resting spore smooth, spherical to ovoid, 8–40  $\mu$ , thick-walled, light to dark brown, with one large globule and a parietal layer of smaller ones; germination unknown.

Saprophytic in leaves of wheat, corn, rye, oats, and various grasses, in Chapel Hill, North Carolina, New York City, and London, Canada.

Septochytrium nov. gen. (fig. 2) is characterized by a heavy rhizomycelium with septations, constrictions and trabeculae or plugs, and by intercalary swellings. Since, on different hosts and even on the same host, it evinced extreme variability in size and shape of sporangia, in degree of polycentricity in number of septations, constrictions and swellings, it has been given the name S. variabile and has been studied from a single spore strain only.

Septochytrium gen. nov. Rhizomycelio intramatricali, praecipue polycentrico, filamentis elongatis, cylindricis, septatis atque constrictis, incrementis intercalaribus, rhizoidibus minutissime ramosis atque variatim formatis, zoosporangiis intercalaribus atque terminalibus, operculatis, cum uno (nonnunquam compluribus) isthmo variatim elongato. Zoosporis cilio posteriore praeditis, emergentibus cumulo vel globoso vel ovato atque quiete aliquamdiu manentibus mox rapide atque emicatim enatantibus. Sporis perdurantibus terminalibus atque intercalaribus, eodem loco quo sporangia formatis vel ab incrementis intercalaribus; germinatione per porum parietis recto itinere in zoosporangium operculatum evanescenti zoosporangio simile, vel in tubulam in cuius apici contenta collecta atque septo separata ut zoosporangium fiat.

Septochytrium variabile sp. nov. Fungus saprophyticus; zoosporangiis hyalinis vel subfuscis, globosis, 4–150  $\mu$ dia. (saepe 75-150  $\mu$ , plerumque 45-60  $\mu$ ) cum papilla vel isthmo curtissimo atque latissimo, ovatis, ovalibus, late pyriformibus,  $10 \times 15 \mu$ -180  $\times$  220  $\mu$  (plerumque 100  $\times$ 150  $\mu$ ) cum isthmo 4  $\mu$ -60  $\mu$ , obclavatis vel vasculiformibus,  $2 \times 6 \mu - 35 \times 360 \mu$ , calyciformibus, irregularibus, ramosis, depressis, cum una (compluribus rarius) papilla vel tubula exeunte varia longitudine atque diametro; zoosporangiis septis maturitate disjunctis, primum pariete levi, maturitate striata vel stratificata, corrugata senente; orificio operculi circulari, 1-16  $\mu$  dia. vel subovato 4 imes 6- $6 \times 10 \,\mu$ . Zoosporis hyalinis, globosis vel ovalibus, 4-6  $\mu$ , cum uno globulo refractivo .7-3  $\mu$  (plerumque 2  $\mu$ ) dia.; cilio 30-40 μ long. Rhizomycelio crasso, extenso (20 μ-1 cm.), maxime ramoso, cum constrictionibus atque septationibus vel trabeculis vel partim vel ex toto trans rhizoides extensis; in sporangiis inserto locis 1-12; diametro loco insertionis .4-10 \mu. Incrementis intercalaribus univesicularibus, singillatim vel seriatim locatis, ovalibus,  $8 \times 10-55 \times 100 \,\mu$  (plerumque  $15 \times 20 \,\mu$ ), interdum globosis, 8-25  $\mu$  dia., fusiformibus  $6 \times 26-20 \times 80 \mu$  vel irregularibus; incremento nonnunquam aucto in zoosporangium secundarium vel tertiarium vel in sporam perdurantem transformato, nonnunquam origine primaria permaxima thalli permanente, sed interdun (ut vedetur) in cellulas duas diviso, altera in sporangium transformata vel in sporam perdurantem, altera apophyside quadam permanente plerumque vacuo vel subvacuo mycelii incremento persistente. Cellulosa reactione in parietibus sporangii, inque incrementis intercalaribus conspicua. Sporis perdurantibus pallidis vel atro-sucineis coloratis, globosis, 4-60  $\mu$ , ovatism  $4 \times 6-50 \times 65 \mu$  vel elongatis,  $10 \times 35 \mu$ ,

Fig. 2. Mature thallus of Septochytrium variabile showing polycentric nature. The large central body is a young primary zoosporangium. Radiating from it is the rhizomycelium with its swelling and secondary zoosporangia. Drawing made with Spencer camera lucida.

levibus, stratificatis, vel cum extera pariete irregulari, interdum cum uno maximo globulo refractivo cumque globulis minoribus numerosis; zoosporangiis directa germinatione sporae perdurantis formatis, globosis, pyriformibus, ovatis, etc., plerumque minoribus quam sporis perdurantibus, zoosporangiis in tubula extrema, ovatis, globosis, pyriformibus vel clavatis; tubula lata atque sacculata vel angusta, longa atque spiriformi,  $7 \times 26~\mu$ – $10 \times 450~\mu$ .

Septochytrium gen. nov. Rhizomycelium intramatrical, predominantly polycentric, consisting of elongate, septate and constricted filaments, intercalary swellings and finely branched rhizoids. Zoosporangia variously shaped, operculate, terminal and intercalary, with one (occasionally several) neck of variable length. Zoospores posteriorly uniciliate, emerging in a globular to ovoid mass and lying quiescent for a few moments before swimming away; method of swimming rapid and darting. Resting spores terminal or intercalary, formed in the same position as the sporangia or from the intercalary swellings; germination through a pore in the wall to form an operculate zoosporangium similar to the evanescent one or a tube at whose tip the contents are concentrated and cut off by a cross wall to form the zoosporangium.

Septochytrium variabile sp. nov. Zoosporangia hyaline to pale brown, spherical, 4-150  $\mu$  in diameter (often 75- $150 \mu$ , average  $45-60 \mu$ ) with a very short, broad papilla or neck, ovate, egg-shaped, broadly pyriform,  $10 \times 15 \,\mu$ -180  $\times$  220  $\mu$  (commonly 100  $\times$  150  $\mu$ ) with neck 4  $\mu$ -60  $\mu$  wide, obclavate to flask-shaped,  $2 \times 6-35 \times 360 \,\mu$ , bell-shaped, irregular, flattened and depressed with one (rarely several) broad exit papilla or neck of varying diameter and length; zoosporangia delimited by true septa at maturity, sporangial wall smooth when young, striated or layered at maturity, wrinkled when empty; orifice of operculum circular, 1-16  $\mu$  in diameter, or slightly oval,  $4 \times 6-6 \times$ 10 μ. Zoospores hyaline, spherical to oval, 4-6 μ, with a single refractive globule, .7-3  $\mu$  (usually 2  $\mu$ ) in diameter; cilium 30-45 µ long. Rhizomycelium coarse, extensive (20 µ-1 cm.), richly branched, with constrictions and septations or trabeculae extending partially or entirely across the rhizoids; inserted on the sporangia at 1-12 points; diameter at point of insertion .4-10 \mu. Intercalary swellings usually persistent as empty or partially empty enlargements of the rhizomycelium but often becoming enlarged and transformed into secondary or tertiary zoosporangia or into resting spores, occasionally acting only as a very large, primary center of organization of the thallus and sometimes seeming to divide into 2 cells one of which enlarges and becomes a zoosporangium or resting spore while the other remains as a sort of apophysis. Treatment with chlor-iodide of zinc giving a pronounced violet color in the sporangial walls and intercalary swellings. Resting spore light to dark amber, spherical 4–60  $\mu$ dia., ovoid  $4 \times 6-50 \times 65 \mu$ , or elongated,  $10 \times 35 \mu$ , thickwalled, smooth, layered, or with outer coat rather irregular, usually with one large refractive globule and numerous smaller ones; zoosporangia formed in direct contact with the resting spore at germination spherical, pyriform, ovate, etc., usually smaller than the resting spore; zoosporangia cut off at the end of a tube from the resting spore oval, round, pyriform or clavate; tube wide and saccate or narrow and long with twists and coils, 7-26  $\times$  $10-450 \ \mu.$ 

Saprophytic on various grasses, wheat, rye, oats and corn leaves and narcissus root tips in Chapel Hill, North Carolina, New York City and London, Canada.

The erection of a new genus for this fungus may be controversial. In size and appearance of zoosporangia as well as in their diversity of shape there is a similarity to Endochytrium operculatum as described by Karling (1937). However, the latter is a monocentric form. While Endochytrium ramosum Sparrow is figured as polycentric, the genus itself is characterized as lacking swellings on the mycelium. Megachytrium, a new genus described by Sparrow (1933), possesses "intercalary swellings marked off by cross walls" and "occasionally septate" mycelium. But the mycelium is "never rhizoidal." Obviously a member of the Cladochytriaceae, our fungus is perhaps most nearly related to

the operculate genus Nowakowskiella. Yet the absence of a swollen apophysis, proliferation of sporangia, and the extramatrical growth habit of the rhizomycelium characteristic of this genus militate against the inclusion of our fungus in it. Contrarily, the great size, the abundance and character of resting spores, and most especially the constricted and septate appearance of the rhizomycelium make it seem prudent for the present to adopt a new generic name.

#### SUMMARY

A new genus, Catenochytridium, is proposed for an operculate chytrid with a catenulate, compound apophysis and the endo-exogenous method of growth. The type species, C. carolinianum, occurs saprophytically in leaves of grass, and cereal grains in association with other chytrids.

A second new genus, Septochytrium, is suggested for an operculate, polycentric chytrid having a coarse rhizomycelium, with constrictions, septations and intercalary swellings. The type species, S. variabile, occurs saprophytically in leaves of grass and cereal grains. It is extremely variable in form and size.

These two chytrids have been separated from five others with which they were originally associated and subsequently cultured in "unifungal" state under as nearly sterile conditions as possible.

# SUGAR EXCRETION IN IMPATIENS SULTANI<sup>1</sup>

Miriam G. Groner

The excretion of sugar by members of the species *Impatiens Sultani* was first noticed in plants that were kept in the laboratory for general use. As no mention of the property was found in the literature, a study was made of conditions controlling sugar excretion and of the chemical nature of the sugar.

I. Sultani has been grown extensively under glass and as a house plant since a few years after its introduction from Zanzibar by Sir John Kirk (Hooker, 1882). The species was originally described by Hooker (1882), and the first American description

was in Vick's Magazine (1884).

EXPERIMENTAL PROCEDURE.—Under experimental conditions some of the plants were grown in a greenhouse, and others were kept on the window sills of a room in which the humidity was relatively low. The size of the individual granules of accumulated sugar was greatest on plants in windows receiving sunlight, but fair accumulation was obtained even on those plants kept in north windows. In the greenhouse, accumulation was good as long as the humidity was low. In cloudy weather, however, the humidity was often too high to permit rapid evaporation of water from the droplets of sugar solution that were excreted. Even in clear weather, the hu-

<sup>1</sup> Received for publication May 22, 1939. These experiments were conducted in the botanical and chemical laboratories at Bucknell University, and this opportunity is taken to express sincere appreciation for

the use of facilities.

midity was at times too high to permit rapid evaporation. All the plants were supplied with plenty of water from below.

The plants used were all grown from cuttings of three parent plants—one with solid green leaves and rose colored blossoms, one with solid green leaves and salmon blossoms, and one with leaves variegated green and white, and rose blossoms. Sugar was first noticed on a plant of the salmon variety, which was obtained in North Carolina. The other varieties were obtained later in Pennsylvania.

If the cuttings were well rooted when potted, good sized sugar granules were usually obtained within two or three weeks in a dry atmosphere. The best yields of sugar were obtained after the plants had become well pot-bound. Usually the sugar was not collected until the leaves were ready to be dropped from the plant by abscission, for at that time the granules were of maximum size and were completely solidified. Granules on leaves that were active photosynthetically were difficult to handle, as they were frequently solid and crystalline on the surface, but liquid in the center.

Figure 1 shows a branch from a plant of the salmon variety that was grown under conditions favorable to sugar accumulation. It may be observed that the sugar is excreted at the tips of hair-like protuberances located on the sides of the petioles, and to a lesser extent from the tips of the serrations on the margins of the leaf blades. These protuberances are

Fig. 1. Branch of Impatiens Sultani showing well-developed granules of sugar (natural size).

multicellular in structure and appear to be modified leaf serrations, each with a hydathode at the tip.

The mechanism of excretion is apparently similar to that causing exudation from the leaf tips of cereals and other plants having hydathodes, but is more active as excretion occurs as long as the roots are well supplied with water, regardless of the degree of saturation of the atmosphere. Relationship to root pressure and to growth substances has not been investigated as yet.

Sugar is apparently excreted under all conditions favorable to photosynthesis but is conspicuous only under conditions favorable to its accumulation. Out-of-doors, sugar is either washed away by dew or rain as soon as it appears or is eaten or carried away by insects. At the same time that sugar is being excreted, starch is being formed in large quantities within the leaf.

Plants with leaves bearing sugar that were kept in the dark for a period of three weeks did not show any marked etiolation, although almost complete abscission of sugar-bearing leaves occurred within a few days.

The best yields of sugar were obtained in a dry atmosphere when the temperature was between 21°C. and 27°C., and the plants were supplied with plenty of water from below. Too high a temperature in a dry atmosphere seemed to retard the rate of growth, but in a moist atmosphere the plants thrived at temperatures up to 33°C., or even more. The plants did well at temperatures as low as 10°C.

For analysis the granules of crystalline sugar were collected from time to time in weighing bottles of known weight, and the bottles of sugar were kept in a desiccator until a constant weight was obtained. A separate bottle was used for each variety. Before the sugar was subjected to chemical analysis, the weight of individual granules of the three varieties was determined. The granules obtained from the variety with green leaves and salmon blossoms varied in weight from 0.0007 g. to 0.0041 g. (average of 12—0.0024 g.); those from the variety with green leaves and rose blossoms varied from 0.0006 g. to 0.0044 g. (average of 12—0.0022 g.); and those from the variety with variegated leaves ranged from 0.0002 g. to 0.0016 g. (average of 12—0.0007 g.).

Plants from which these granules were collected were kept under identical greenhouse conditions, and the selection was representative as to size. The average weight of the granules produced by the varieties with solid green leaves does not vary appreciably. However, those produced by the plants with variegated leaves are very much smaller than those obtained from either of the solid green types. In variegated plants, no sugar is excreted by pure white leaves, and most of the granules are produced by leaves having comparatively large green areas.

The figures regarding the two green types apply only under optimum conditions for sugar formation. Actually, the salmon variety produces appreciable quantities of sugar under a much wider range of conditions than the rose variety. No quantitative determinations of the amount of sugar produced un-

der varying conditions were made, as accurately controlled conditions could not be obtained.

Chemical analysis.—Sugar from all three types was tested qualitatively with the Foulger (1932) reagent containing urea. Samples from all three varieties gave a deep blue-green color on boiling with the acid reagent, indicating that the Impatiens sugar yielded large quantities of levulose on hydrolysis. This indicates that the original substance must contain a large proportion of either sucrose or inulin, and inulin is ruled out by the extreme solubility of the excreted granules in water and by additional and more conclusive evidence obtained through hydrolysis of the sugar, as shown in figure 2.

When a gram or so of sugar granules from each of the two green varieties had been collected, the bottles containing them were placed in a desiccator until a constant weight was obtained. This was necessary, as the freshly collected granules contained some water. The sugar was then dissolved in about 25 ml. of distilled water. Solid impurities, such as portions of dried petiolar hairs and dust, were removed by filtering the solution through a weighed Gooch crucible. The weight of dry impurities was deducted from the original weight of sugar before the percentage composition of the solution used in analysis was calculated. The filtered solution was diluted to a volume of exactly 50 milliliters. Approximately half of this was used to determine the specific rotation of the sugar (Rolfe, 1919), and the remainder was used to determine its molecular weight by the freezing point method (Findlay, 1926).

The rotation of polarized light by the sugar solution was measured with a saccharimeter of the Ventzke type, and the specific rotation calculated

Table 1. Specific rotation and molecular weight of sugars from Impatiens Sultani, compared with the known specific rotation and molecular weight of common sugars.

Invert sugar		180

by the usual formula (Rolfe, 1919). All readings, except those during hydrolysis, were taken at 20°C.

The freezing point of the sugar solution was determined by the Beckmann method (Findlay, 1926), and the molecular weight of the sugar calculated from this value.

The results of these determinations, as well as some additional ones are given in table 1. Comparable known factors for the commoner sugars, as taken from the Handbook of Chemistry and Physics (Hodgman, 1936) are also included in this table.

For hydrolysis, a solution of mixed sugar from the salmon and rose varieties of *I. Sultani* was prepared by the method described above. A solution of cane sugar of similar concentration was also prepared. Hydrochloric acid was added to the sugar solutions in the proportion of 0.25 ml. to 50 ml., so that the resulting solutions were approximately

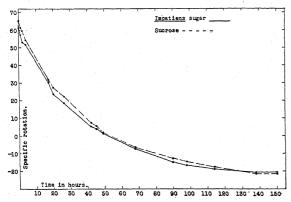

Fig. 2. Inversion curves obtained from the hydrolysis of *Impatiens* sugar, and can sugar with .05 M. HCl, at 95°C

0.05 M. for both sugar and acid. The optical activity of both solutions was measured at intervals during the period of hydrolysis, and the results are plotted in figure 2. The curves are typical of this type of irreversible reaction, in which the velocity of the reaction decreases proportionally as the concentrations of the reacting substances diminish (Findlay, 1926). The first reading was taken at room temperature, 22°C., and subsequent readings were taken at the temperature, 25°C., of the constant temperature bath in which the tubes of sugar solution were kept throughout the duration of the experiment, except for a few minutes required for readings. It may be observed that the curve for the Impatiens sugar is almost identical with that for cane sugar.

Discussion and conclusions.—The figures given in table 1, and the inversion curves shown in figure 2, indicate that the sugar excreted by *I. Sultani* is mostly sucrose, but probably contains a very small proportion of optically active impurity, possibly dextrose. Dextrose is suggested as a probable impurity because it would theoretically produce approximately the degree of error observed, and its presence would seem logical.

The values obtained for molecular weights are probably not as dependable as the specific rotations, as no attempt was made to remove soluble impurities from the original solutions. Any trace of ionizable substance of course produces a disproportionately large error in the freezing point. In determination of specific rotation, only optically active impurities are a source of error.

Values for specific rotation of recrystallized sugar very closely approach the theoretical values for cane sugar. The sugar was recrystallized by evaporating the water from the original solution in an oven at 80°C. The freezing points of the solutions of recrystallized sugar were not determined.

The sugar from the variegated plants was not subjected to quantitative analysis, as it was impossible to obtain a large enough sample within a reasonable time from the few plants available. The results from the other two varieties indicate that they both produce the same general type of sugar. Qualitative tests and physical properties would indicate that the sugar from the variegated plants is of a similar nature.

The observations reported indicate that the sugar excreted by *Impatiens Sultani* is in excess of the amount necessary either for immediate use in respiration and protein synthesis, or for storage in the form of starch. The points in favor of this conclusion are first, that the quantity of sugar excreted is generally proportional to the amount of sunlight available, and to the amount of chlorophyll present in the leaves. Second, that the greatest amount of sugar is excreted after the plants have become well potbound, at which time vegetative growth is somewhat retarded. Other factors being equal, the amount of sugar excreted was observed to vary roughly with the temperature, although there are no quantitative data on this point at present.

The plants seem to develop most luxuriantly under conditions where the excreted sugar is kept from accumulating, either by natural forces or by spraying the leaves with water. However, accumulation of sugar does not injure the plant, but merely seems to induce early abscission of sugar laden leaves. Indirectly, the plant may be injured by the numerous insects that are attracted by the sugar.

It is suggested that the excretion of sugar by I. Sultani tends to keep the concentration of carbohydrates within the plant at an optimum level. Physically the plant is of a succulent type and thrives out of doors either in full sunlight or in total shade. The plant not only grows vegetatively, but also blossoms freely in any situation where the moisture supply is adequate. The largest number of blossoms are produced in sunlight, but leaf development is at its best, and the blossoms reach their greatest individual size in partial shade, preferably with sunlight filtering through trees. Assuming that the plant is a shade plant in its native condition, the excretion of excess sugar would enable the plant to tolerate photosynthetic conditions under which more carbohydrates are produced than can be used or stored at the saturation point of the plant's tissues. This statement in no way implies that the sugar is toxic to the plant, but merely that there may be a saturation point, above which more sugar interferes with the osmotic equilibrium of the cells.

Whether or not sugar excretion occurs in other members of the genus *Impatiens* is not known, but it did occur more or less extensively in the three varieties of *I. Sultani* that were studied. In many respects this report is preliminary in nature, and the author would be interested in communicating with anyone having additional information or material.

#### SUMMARY

A solution of comparatively pure cane sugar is excreted through the petiolar hairs of the three varieties of *Impatiens Sultani* that were studied. Wherever conditions are such that the droplets of solution are not immediately removed by natural forces or artificial watering, they gradually increase in size, and lose water through evaporation until granules of crystalline sugar are formed. These granules are clean and white in appearance and have the flavor of raw cane sugar. Chemical tests—

determination of specific rotation, molecular weight, degree of inversion, and qualitative tests with the Foulger reagent—indicate that these granules are composed mostly of sucrose, mixed possibly with very small portions of dextrose. As sugar is excreted, starch is formed in large quantities within the leaves.

The quantity of sugar excreted varies with the amount of sunlight available to the plant, and less noticeably with the temperature. Varieties with leaves that are variegated green and white produce only very small quantities of sugar as compared with the commoner types with solid green leaves. The greatest amount of sugar is produced after the plants have become well pot-bound.

Although *I. Sultani* is a native of tropical Zanzibar, it has proved to be unusually adaptable to varying conditions under cultivation in the temperate zones, thriving and blooming in either sun or shade. The ability of the plant to excrete excess sugar is suggested as a possible explanation of this unusual adaptability.

# THE ACTION OF ULTRAVIOLET RADIATION ON DERMATOPHYTES. II. MUTATIONS INDUCED IN CULTURES OF DERMATOPHYTES BY EXPOSURE OF SPORES TO MONOCHROMATIC ULTRAVIOLET RADIATION <sup>1</sup>

C. W. Emmons and Alexander Hollaender

It has been known for several years that variants can be induced in fungi by suitable exposure to ultraviolet radiation (Smith, 1936). We will present in this paper measurements of the fungicidal action of monochromatic ultraviolet radiation and the correlation observed between the systematic appearance of large numbers of variants and both the wavelength and energy of the inciting radiation. We believe that variants of the order to be described, because of their characters and permanence, repre-

<sup>1</sup> Received for publication May 15, 1939.

This material was presented in a paper at the Richmond meetings of the Mycological Society of America and as a demonstration before the Genetics Society of America, December 28 and 29, 1938. See Genetics 24: 70-71, 1939.

We wish to express our thanks to Dr. F. S. Brackett, National Institute of Health, Washington, D. C., and to Dr. M. Demerec, Carnegie Institution of Washington, Cold Spring Harbor, for careful reading and criticism of this paper. sent true genetical changes, and we shall accordingly refer to them as mutants

ingly refer to them as mutants.

The fungus used is a strain of Trichophyton mentagrophytes isolated from dermatophytosis ("ringworm") of the arm. It resembles the variety often referred to as T. asteroides (fig. 3) and is a typical dermatophyte (Emmons, 1934). In another paper (Hollaender and Emmons, 1939) we are reporting the lethal effect of monochromatic ultraviolet radiation between 2,280 and 2,950 A upon spores of another strain of the same species isolated from dermatophytosis of the foot ("athletes' foot"). Information about the relative fungicidal values of different wavelengths for fungi in vitro may lead to increased efficiency in the therapeutic use of ultraviolet.

Although the rate of appearance of mutants in pure cultures of fungi can be increased by exposure to ultraviolet radiation and other external forces such as X-rays, heat, and chemicals, mutations may

ccur independently of such influences. The sponaneous production of mutants is a prominent feaure of the dermatophytes. In some strains, if subultures are made from atypical spots which appear n the surface of old colonies, mutants differing ridely from the parent type can be easily isolated Emmons, 1932). In the present experiments we sed voung cultures in which spontaneous mutation ad not occurred. The possible significance of sponaneous and induced mutation in the classification of he dermatophytes will be discussed later.

EXPERIMENTAL TECHNIQUE.—As in the other tudies reported, the spores were suspended in a alt solution which had no measurable absorption or the wavelengths used (2,280-2,950A). The denity of the suspension was adjusted in most cases so hat there were about seventy million spores per ubic centimeter. A water cooled, high pressure, uartz capillary, mercury vapor lamp was used as he source of ultraviolet radiation. The radiation assed through a quartz monochromator, thence hrough a quartz window into the exposure cell there the spore suspension was rapidly and contantly stirred. For details of the methods used see Hollaender and Claus (1936). The density of the pore suspension insured that all radiation, direct nd scattered, was absorbed.

It was investigated separately whether or not our echnic of irradiating liquid suspensions was justied, and it was found that in the concentration used n these tests (about 70 million spores/cc.), depth f cell (2 cm.), size of cell (8 cc.), and with thorugh stirring the incident energy divided by the umber of spores will give the average energy each pore received. Details of these tests will be pubshed separately.

Before exposure 0.1 cc. of the spore suspension as withdrawn with a sterile pipette from the free rm of the exposure cell, suitably diluted in physioogical salt solution, and plated out. A control of is sort was set up for each experiment and for each ifferent wavelength in a given experiment. During ne exposure, similar 0.1 cc. samples were removed t appropriate intervals and plated out in the same lanner on corn meal agar plates. These were inibated at 30°C. or at room temperature for five or x days. The colonies which developed were counted order to determine the survival ratio. After the irvival count was recorded, all colonies from a iitably diluted plate or plates were separately subiltured to slanted culture tubes of modified Sabouud's agar.2 The transfer to slants revealed any renotypic changes which had been induced by ulaviolet radiation. Such isolation of exposed spores as necessary because most of the induced mutants ow more slowly than the normal and would have en overgrown by neighboring colonies on the origiil plate.

<sup>2</sup> The ingredients of Sabouraud's medium being unobinable, a number of peptones were tested. Neo-peptone, product of the Difco Laboratories, and C. P. dextrose ere found to be satisfactory substitutes. Some dermatolytes, however, do not grow in exactly characteristic ittern on this medium.

Usually 80-100 colonies from a given "run" (i.e., a planting from one exposure interval at a given wavelength) were thus transferred. This was, in effect, a random sampling of the spores which had been exposed to radiation. The number of "runs" varied with different experiments, but in some individual experiments 2,200-2,700 colonies were picked from plates and transferred individually to slants for observation of their development. In all, some 13,000 colonies, representing equivalent samples of 15 billion spores, have been so handled in obtaining the accompanying data. It was found that numbers of this magnitude were necessary in order to obtain reproducible and statistically significant results.

In studying variation phenomena one must be sure that the original material is in pure culture and that what appears to be the origin of mutants is not actually the dissociation of two unlike strains at first carried along together. In part of these experiments the plating out method was used to insure purity of the strain; but in later experiments single spore isolates were used. Previous studies have indicated that the spores are uninucleate, as well as unicellular. Single spore isolates were also made from many of the mutants when they appeared. This refinement in technique, so far as we could determine, did not alter the results.

RESULTS.—Two sublethal effects were observed. The first was a retardation of germination. This was always apparent by comparison with control plates and was checked by measurements of the germ tubes of spores made at appropriate intervals and in a suitable number of microscope fields on control and irradiated plates. This was a temporary physiological effect which disappeared on subculturing. Temporary effects of this type are not indicated on either the charts or the table accompanying this paper. To determine the mutation rate in these slowly growing spores, 425 retarded and very small colonies were picked under the dissecting microscope. Only three of these differed from the normal colony type on subculture. This appears to be a considerably lower rate of variation than was observed in random sampling. The significance of this apparent decrease in rate is not yet clear.

Besides these temporary changes, however, we observed other alterations which apparently are permanent. Permanent variations or mutations of the latter type may appear spontaneously in old cultures or they can be induced in young cultures or spores by exposure to ultraviolet radiation or other influences. One type of growth appears so constantly as a variant in old cultures of dermatophytes that, following Sabouraud, it is referred to by medical mycologists under the special name of "pleomorphism." This variant is a more or less sterile white mycelial growth which is less virulent for animals and may correspond, in a general way, to variants of some pathogens of plants in which virulence is similarly reduced. Spontaneous mutations in these fungi is by no means limited to one type of change, and if properly searched for in old cultures,

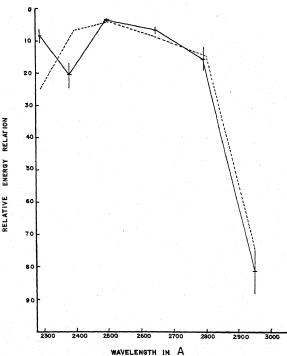

Fig. 1 (above). Lethal effect (upper curve) and production of mutants (lower curve) following exposure of spores of *Trichophyton mentagrophytes* to monochromatic ultraviolet radiation of wavelength 2,650A.

Fig. 2 (below). Wavelength dependence of lethal effect (dotted line) and mutant production (solid line) when spores of *T. mentagrophytes* are exposed to monochromatic ultraviolet radiation.

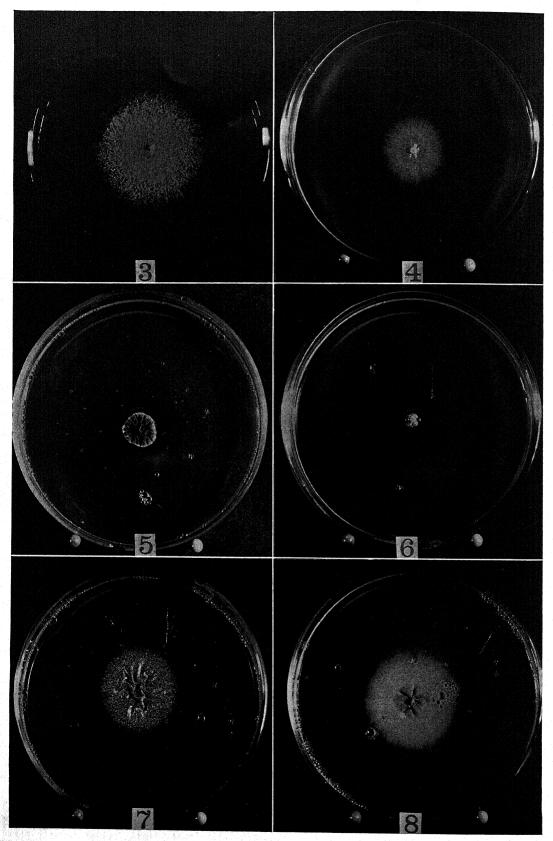

Fig. 3-8.—Fig. 3. Ten-day culture of the strain of dermatophyte used. All cultures in the entire series are of the ame age and grew under identical environmental conditions.—Fig. 4-8. Ten-day cultures of mutants of the strain hown in fig. 3, belonging in Group II.

mutants differing from the parent in colony type, color, morphology, etc., can be found and isolated (Emmons, 1932). No mutants of any type appeared in our control cultures (isolations from nonirradiated spores), which numbered over 2,000. This is explained by the fact that we took care to use only young vigorously growing cultures in preparing the spore suspensions. When, in a later experiment, subcultures were made from pigmented and otherwise atypical spots of growth on old cultures of this strain, we were able to isolate mutants resembling some of those induced by ultraviolet radiation. Some of them were widely divergent types similar to the violaceum-like mutant shown in figure 5.

The induced mutants isolated in this study differ from the parent strain, and, with few exceptions. from each other in degree or type of pigmentation, in rate of growth, or in the amount and type of aerial hyphae produced. Table 1 indicates in tabular form the number and percentage of mutants which have been isolated after exposure of spores to the different wavelengths. The table does not show the amounts of energy to which the spores were exposed, however. The quantitative evaluation of energy required is given in the section immediately following. In order to simplify the discussion, the appearance of the different types of mutants and their classification into groups will be given after the presentation of the quantitative response. It is necessary to state here only that so far as we have determined, there does not appear to be any positive correlation between either the wavelength or the amount of energy used and the resulting type of induced mutation.

Quantitative response.—The graphs in figure 1 demonstrate results obtained in a typical experiment when one wavelength band (2,650A) was used. The upper curve, indicating survival ratio, was obtained in the manner described in our previous publication (Hollaender and Emmons, 1939). The lower curve shows the number of variants produced per 100 spores surviving exposure at energy levels given along the base line. A vertical line drawn from the points on the survival ratio curve (upper curve) to the variant curve (lower curve) indicates the actual number of variants produced at

corresponding survival ratios. For detailed data on this graph see table 2. Such graphs have been obtained for six different wavelengths between 2,280A and 2,950A. However, we have not determined as many points for some of the wavelengths as are given in this graph. In each experiment testing six different wavelengths we used a single batch of spores. This is necessary because there is some variation between different batches of spores.

Knowing the energy necessary to produce the maximum number of mutants, we calculated the amount required to produce a single mutant. These values for the six different wavelengths are plotted against wavelength in figure 2. The solid line gives the relative efficiency of different wavelengths in producing these mutants. The values are from three sets of experiments covering the entire range of wavelengths. This figure also includes a curve (dotted line) showing the efficiency of killing at different wavelengths for 50 per cent survival ratio.

Description of mutants.—We have attempted, for the sake of convenience, to classify the mutants induced by ultraviolet radiation into the six groups shown in table 1. This can be done in a general way only, because of the great variety of forms observed. Some could have been placed in either of two of the groups arbitrarily established. The most obvious character is that of color. The mutants are, therefore, grouped primarily according to an increase or decrease in pigment production; secondarily, according to presence or absence of aerial hyphae and spores.

Mutants which differed only slightly from normal are included in Group I, shown in the first double column. Most of these grew at a slower rate and produced somewhat more pigment than normal, but the differences were so slight as to make it questionable in many cases whether a given strain should be set apart from the normal. Furthermore, some of these changes were not permanent, and strains originally placed in this group contributed largely to the size of Group VI, which will be discussed later. Strains characterized by a marked increase in the amount of pigment produced by the fungus were placed in Groups II (fig. 4-8) and III (fig. 9-12). They include the majority of the mutants observed. In almost all cases the pigment was of the same wine color as that produced by the normal strain, but more intense or increased in amount. In a few cases a golden pigment was produced, and, in a few, a dark diffusible pigment. The groups are separated by the degree of development of aerial hyphae, members of Group II being nearly or quite glabrous. Groups IV (fig. 13) and V (fig. 14) are characterized by decreased pigment production and differ from each other by lack or by possession of aerial hyphae.

Group VI includes those strains which have apparently reverted to normal, and it requires more detailed consideration. At the time this analysis was made, 7.5 per cent of the variants originally picked had apparently reverted. As pointed out above, most

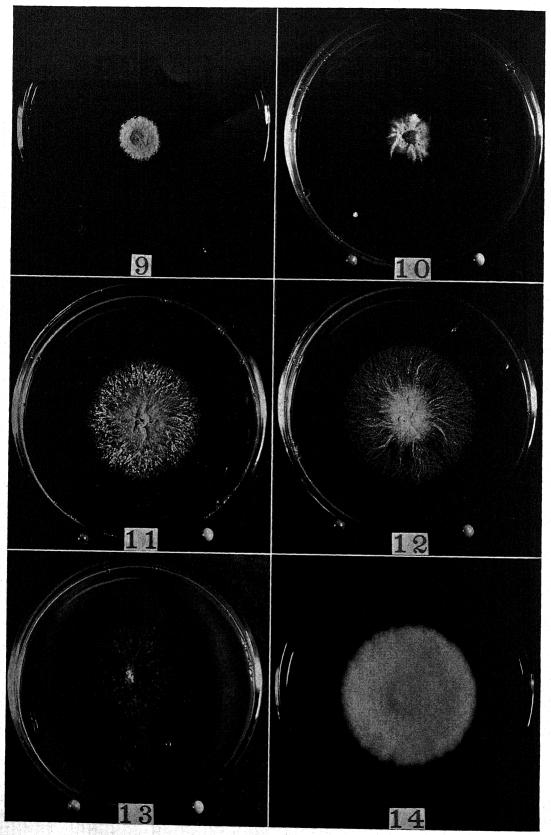

Fig. 9-14.—Fig. 9-12. Mutants of the same strain, belonging in Group III.—Fig. 13. Mutant of the same strain, belonging in Group IV.—Fig. 14. Mutant of the same strain, belonging in Group V.

of these had at first been placed in Group I because they differed only slightly from the normal. In some cases the the differences which prompted their selection were temporary, as well as slight, and probably these strains should never have been selected as mutants. There is another possible explanation for apparent reversion. In the search for mutants all colonies on a dilution plate were separately transferred to slants. It is probable that some of these colonies arose, not from a single spore, but from two or more which had clumped. If one of these spores had mutated, its growth in the heterogeneous colony would have stamped the whole colony as a mutant. However, almost all the mutants grow more slowly than normals, and in subsequent transfers of the heterogeneous colony the faster growing component (that is, the normal) would eventually be unintentionally selected, and the slowly growing mutant would be eliminated. We attempted to avoid this error by making single spore isolations of the mutants soon after their isolation. Of 52 so treated, and carried thereafter as single spore isolates, none have reverted, although two have further changed to a "pleomorphic" mycelium. A part of these 52 strains have been subcultured as many as ten times over a period of several months.

Single spore isolates of an additional series of 50 representative mutants selected at a later date and subcultured twenty times over a period of eight months have not reverted. It appears, therefore, that the mutants listed here are permanent in the same sense that the normal fungus is permanent. That is, if properly cared for, the characteristic culture and morphologic features are reproduced with fidelity in an indefinite number of subcultures, the only exceptions being further mutations which occur very infrequently in young cultures.

DISCUSSION.—It has been generally accepted that in the X-ray region increased energy will produce increased percentage of mutations, at least in higher organisms (Timofeef-Ressovsky, 1937). Our results, as illustrated in figure 1, show that with increasing energy in the ultraviolet range the percentage of mutants among surviving individuals after reaching a maximum will decrease.

The wavelength dependence curve as given in figure 2 for mutant production shows a definite maximum at 2,650A and 2,537A, where the probable error is small. The apparent decrease in efficiency at 2,380A, where the probable error is greater, may be less than is indicated by the curve. The maximum at 2,537-2,650A may be significant because it is at this wavelength that nucleic acids have their most intense absorption band (Caspersson, 1936). Proteins have a slight absorption at 2,805 but increased absorption at wavelengths below 2,400A. The nuclei of these spores are very small and do not lend themselves to cytological studies, but it has been shown that in the salivary gland chromosomes of Drosophila (Caspersson, 1936) the nucleic acids and proteins occupy definite and localized bands in the chromosomes. The greater efficiency in the 2,600 region, both in lethal and sublethal action, may indicate that the nucleic acidcontaining components of the chromosomes are most susceptible to changes and that these changes in them may effect the inherited characters of the cell. Conclusions based on such indirect evidence must be accepted with considerable caution. It is possible that other labile compounds which have the same absorption bands as nucleic acid are also present in the chromosome, but in such small quantities that they have escaped detection. It may be too that protein structures, otherwise vulnerable to injury at the shorter wavelengths, are protected by morphological structures in the cell.

The permanence, as well as the character of observed mutants, raises the question of the suitability of these fungi as material for genetical studies. Mycologists have usually avoided the word mutation for the fungi, preferring to use such terms as saltation and variation to indicate sudden changes appearing in these microorganisms in which the nuclear structure is imperfectly known. No sexual type of reproduction is known among the Fungi Imperfecti, to which group this fungus belongs. Since there is no nuclear fusion and no meiosis in the known life history of this fungus, the techniques of inbreeding, back crossing, etc., cannot be used. It is probable, however, that a genotypic alteration is immediately apparent as a phenotypic change. In the experimental work reported here, the material irradiated was a suspension of spores each of which, as indicated by earlier studies, was presumably unicellular and uninucleate. Single spore isolates derived from these uninucleate spores before radiation are identical so far as can be determined. We believe that the striking alterations in growth of some of the surviving spores following radiation represent true genetical changes.

Other explanations have been offered to account for abrupt changes of growth habit. Vegetative hyphal fusions occur in these fungi and give opportunity, if these is a heterocaryotic condition, for interchange between cells. Brierly (1929) believes that most saltations in the fungi are the recombination of characters already present. Recently Hansen (1938) described the "dual phenomenon," a term by which he proposes to designate the dissociation of two culture types which he believes are normally inherent in many Fungi Imperfecti, particularly those with multinucleate cells. His explanation of the phenomenon of variation does not seem adequate to explain the mutations we have observed induced by radiation. The conidia of Trichophyton are uninucleate, and the variants cannot be placed in two, or a few, groups. There is no reason to assume, however, that all the variation (or mutation-like) phenomena observed among fungi have one common explanation.

It does not seem practicable or necessary to describe in detail the mutants here reported. A few should be briefly noted. Several variants, similar to the one shown in figure 14, resemble the *T. inter-*

digitale, and others (fig. 9), the T. granulosum varieties of T. mentagrophytes. The strain shown in figure 5 closely resembles Trichophyton violaceum. It produces the same intense violaceous pigment; the colony is wrinkled, heaped-up, and bears few or no aerial hyphae; and the fungus grows slowly. Several mutants of precisely this type were isolated. Others closely resemble the nonpigmented phase of this same species. This does not necessarily mean that a fungus as well differentiated as T. violaceum is not of specific rank. It is a common and clinically important species in many parts of the world. However, it is not common in the United States, and its rare and sporadic isolation here might conceivably be explained by its occasional appearance as a mutant from another species. It seems apparent, from this and from other considerations, that the dermatophytes form a genetically related group of fungi; and the large number of rather poorly differentiated species in the group, the occurrence of interspecific bridging forms in many long series of isolations, and the appearance of mutants in single spored isolates, can all be interpreted as indicating that the species are highly mutable.

Strikingly different as these mutants are from the parent type, we are confident that they are actually mutants and not foreign contaminants. In the first place, strains of these types did not appear in our controls numbering more than 2,000 colonies. Second, they are obviously dermatophytes, as can be readily determined in all but a very few cases by an examination of the type of sporulation. Many of them, also, as shown by inoculation tests, are still virulent for the guinea pig, but in reduced degrees. By analogy it seems probable that some of those which appear avirulent for this animal are still virulent for man (as in the case with some other species of dermatophytes), but we have not had opportunity to test this.

Finally, in further consideration of the status of these mutants, while it is apparent that they are dermatophytes, we can also be confident that they are not strains (or "new" species) independently isolated from other cases of clinical dermatophytosis. Some of these mutants, it is true, resemble, in some respects, other strains and other species of dermatophytes. However, these latter species were not in culture in the laboratory, much less floating about in the air, at the time these experiments were being carried out, and again we can cite the fact that fungi of this type did not appear among the 2,000 control colonies isolated.

Previous studies have indicated that some mutants of this general type can be isolated from old cultures which have not been exposed to ultraviolet radiation, and the effect of such radiation seems to be to accelerate a process normally operative in these fungi. We have reason to suppose also that such mutation takes place in nature, either in the saprophytic phase of the fungus, when this occurs, or in its parasitic phase in the skin. It is, therefore, reasonable to conclude that this capacity to produce mutants explains in part at least the unfortunate multiplicity of names applied to dermatophytes.

#### SUMMARY

A method of exposing a suspension of spores of dermatophytes to monochromatic ultraviolet radiation is described. The energy was measured so that the amount expended on each spore can be calculated.

When spores of a strain of *Trichophyton menta-grophytes* are exposed in this way, besides the lethal effect, interesting secondary effects are observed, the most striking being mutant production.

Both mutant production and lethal effect are greatest after exposure in the region of wavelengths 2,537 and 2,650A.

Rate of mutations reaches a maximum at certain energy levels (in the case of these spores when exposed to radiation of wavelength 2,650A, the maximum is  $100 \times 10^{-4}$  ergs per spore) and rapidly decreases with increasing amounts of energy (increased time of exposure).

The mutants are placed in six arbitrarily delimited groups. The majority of them show an increase in pigment production and a decrease in growth rate. A few of them are indistinguishable from other species or other varieties of dermatophytes. The mutants are comparatively stable.

No mutants appeared in 2,000 control colonies isolated from nonirradiated spores. However, when spores from an old culture of the original strain were isolated, several mutants appeared, some of them being similar to those induced by ultraviolet radiation. Ultraviolet radiation merely accelerates the rate of mutation.

The significance of mutation in the taxonomy of dermatophytes is considered.

# CARBOHYDRATE TRANSFORMATIONS IN LEAF BLADES, WITH SPECIAL REFERENCE TO SUCROSE SYNTHESIS <sup>1</sup>

# O. A. Leonard

THE PRESENT work represents a continuation of the author's previous studies on the transformation of sugars in plants (Leonard, 1938). The purpose of the present study was to investigate some factors which are important in the synthesis of sucrose. A review of the literature may be found in a recent publication by Nurmia (1935). Daoud and Tadros (1935) review the literature on the mechanisms of hexose transformations.

MATERIALS AND METHODS.—Corn (Zea mays), sorghum (Sorghum vulgare), cotton (Gossypium hirsutum), and cabbage (Brassica oleracea) leafblades were collected and experiments conducted during the summer and fall of 1938. The corn blades were gathered during August from a commercial field of hybrid seed corn at Ames, Iowa. The sorghum samples were obtained from the Agronomy Farm of Texas A. and M. College in September and October. The leaves were gathered from suckers, after the main crop had been harvested. Cotton leaves were taken from a commercial field near Bryan, Texas, also during September and October. The cabbage samples were obtained from the Texas A. and M. Horticultural Farm during November and December.

The leaves were clipped from the plants, their petioles placed in water, and removed to the laboratory. Samples were taken in duplicate and sometimes in triplicate. The sugar feeding experiments and treatment of the materials were handled as previously reported (Leonard, 1938), as were the analysis of corn blades. The sugars in cotton, sorghum, and cabbage samples were determined by a modification of the Munson-Walker-Bertrand method. Nyn's selective method was used for determining fructose (Loomis and Shull, 1937), and sucrose was inverted by invertase. The portions of the blades submerged in the sugar solutions were always discarded.

PRESENTATION OF DATA.—Influence of time on synthesis of sucrose from glucose.—Corn leaf blades were gathered at 6 a.m., August 13, 1938, from

<sup>1</sup> Received for publication April 11, 1939.

This work was made possible by a grant from the

Sigma Xi research fund.

The author wishes to express his thanks to Dr. W. E. Loomis of Iowa State College for his helpful suggestions during the early part of this work and for reading the manuscript. Acknowledgments are also due several members of the Biology Department of Texas A. and M. College who have been of assistance in various ways.

plants whose ears were predominately in the early milk stage. These blades were placed in quart jars containing 300 cc. of 6 per cent glucose solution in a semi-dark hallway in the basement of the botany building at Iowa State College, Ames, Iowa. Hartt (1937), Nurmia (1935), the author (Leonard, 1938), and others have found light not to be necessary for sucrose synthesis. The temperature of the hallway varied between 31° and 35°C.

Check samples were taken at the start of the experiment and after the blades had been in distilled water for 26 hours. There was a decrease of 1.20 per cent in total sugars, 1.83 percent in sucrose, and a gain of 0.63 per cent in glucose of the checks during this period. The midribs were always separated from the rest of the blades and were not included in the analysis.

The graphs of figure 1 show that sucrose increased markedly during the 26-hour period in the blades fed glucose, while the reducing sugars underwent very little change. Loomis (1935), under natural conditions, observed similar fluctuations within corn blades during photosynthesis. There was no fructose until the 14th hour, and then it was pres-

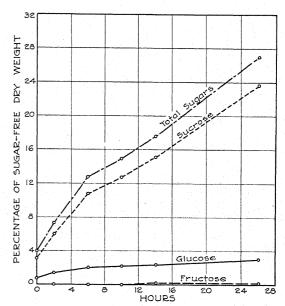

Fig. 1. Changes in the sugar content of corn blades when fed 6 per cent glucose.

ent only in traces. Evidently any fructose which may have been formed from glucose was transformed, with glucose, into sucrose. Corn leaf blades reported in a previous investigation (Leonard, 1938) accumulated more fructose than was found in the present work. The data indicate that a given sugar may be supplied to a tissue or organ and still not accumulate in the unchanged form.

Hartt (1937) found that there was a continuous increase in sucrose, but only a slight reducing sugar response from feeding leaf blades of sugar cane either fructose or glucose for periods up to 24 hours. In general her results on sugar cane were the same as are illustrated in figure 1 for corn blades. Warner (1932) fed *Elodea* leaves with glucose and sucrose and obtained fluctuations of reducing sugars and sucrose similar to those which occurred during photosynthesis.

Synthesis of sucrose from various sugars and sugar alcohols.—In general only glucose, fructose, and sucrose are found in leaves in the uncombined state. Some leaves contain sugar alcohols (Ruhland and Wolf, 1936), and these seem to be more widespread than was formerly believed. Feeding leaves sugars not found to exist in them in the free state is of interest in determining how readily these sugars are transformed into glucose, fructose, and sucrose. It is known that practically any of the sugars or

sugar alcohols will cause leaves floated in solutions of these sugars to form starch. However, all these tests have been qualitative rather than quantitative, and the possibility has not been excluded that the formation of starch may have been due to the effect of some of the sugars on the starch condensing system.

Middle-aged cotton leaves were fed glucose, fructose, sucrose, maltose, lactose, d-galactose, l-xylose, l-arabinose, cellobiose, and d-manitol. Sucrose was formed in abundance from glucose and fructose, to a lesser extent from maltose and lactose, and slightly from cellobiose. Losses in sucrose were observed when the leaves were fed l-arabinose, l-xylose, d-galactose, and d-manitol.

A more complete study of the transformation of the various sugars was made on sorghum leaf blades. For the most part the response of cotton and sorghum to these sugars was the same, and only the sorghum data will be presented. The data are shown in tables 1 and 2. As with cotton, glucose and fructose were readily transformed into sucrose. Lactose and maltose, also, formed sucrose, but the reducing sugar value was high in the lactose feeding experiment. Only a small quantity of sucrose was formed in the d-galactose feeding experiment. Lactose is a reducing disaccharide and contains glucose and galactose. Since acid and invertase hydrolysis of the

Distilled water	1.35	0.40	2.08	0.42

sugar extract yielded practically the same total sugar value, it is concluded that most of the lactose absorbed by the sorghum blades had been hydrolyzed. Evidently the large reducing sugar value for lactose was due to the accumulation of d-galactose, the glucose being used in synthesis of sucrose. Nurmia (1935) noted that only a little sucrose was formed in leaves of the horse bean (Vicia faba) when fed d-galactose. Leaf blades fed d-mannose decreased 1.2 per cent in sucrose during the experiment. Clements (1932) found mannose to be absent from the leaves of 42 species of plants from widely separated families and expressed the belief that mannose could not be the first sugar formed in photosynthesis.

The pentoses l-xylose and l-arabinose brought about no increases in sucrose content of the sorghum leaf blades. The sugar alcohols of d-glucose, d-mannose, and d-galactose, that is d-sorbitol, d-manitol, and d-dulcitol likewise were fed to sorghum blades, and in all cases there was a marked decrease in both total sugars and sucrose. Since galactose and mannose showed little indication of being sucrose forming, one might have expected the corresponding behavior with their alcohols, but a different behavior might have been expected with the glucose alcohol, sorbitol. Evidently none of the sugar alcohols are readily converted into their corresponding sugars, as there was always a marked decrease in total sugars when these alcohols were fed. A slight increase in sucrose was noted when cellobiose was used, although the cellobiose activity of the sorghum blades was very weak.

The reducing sugars were checked roughly to determine whether any appreciable quantities of glucose or fructose were produced from any of the other sugar forms. A mixture of yeast was added to the sugar extracts from the leaves, and these were held for 10 hours in an incubator at 34°C. From two-thirds to three-fourths of the initial reducing values remained for the leaves treated with d-galactose, lactose, l-xylose, and l-arabinose. No doubt there was some loss in the difficultly fermentable sugars, but since there was some reducing sugar (glucose) in the check, no doubt the major loss in reducing value was due to fermentation of this sugar. Nurmia (1935) obtained similar results with l-xylose and d-galactose using specific strains of B. coli in her horse bean feeding experiments.

Although several of the sugars and sugar alcohols were slightly if at all transformed into glucose and fructose in sorghum and cotton leaf blades, there is some evidence that these transformations occur in both the plant and animal kingdoms. A review of the literature on the mechanism of the interconversion of the hexose sugars may be found in a recent publication by Daoud and Tadros (1935). Daoud (1932) and Daoud and Tadros (1935) working with seeds of the fenugreek (Trigonella foenumgraecum) found that during germination the only reserve carbohydrate, a mannogalactan, was completely transformed into glucose and fructose. The mannogalactan yielded on acid or enzyme (seminase) hydrolysis in vitro equal quantities of mannose and galactose.

The sugar alcohols occur commonly in fruits and less often in leaves. Nuccorini and Bartoli (1932) thought that sorbitol was transformed into fructose and glucose in the ripening fruits of Sorbus domestica, and Martin (1937) has recently observed a similar disappearance of sorbital and accumulation of sugars with the ripening of pears.

Senescence and sucrose synthesis.—Senescence is one of the many factors which influence the transformation of carbohydrates within plants. Tables 3 and 4 show the composition of cotton blades fed

glucose, fructose, and sucrose on September 10 (before harvest) and on October 1 (after harvest). The September 10 series converted a little more than one-half of the reducing sugars absorbed into sucrose, while only about one-sixth were thus transformed on October 1. At the earlier date, the leaf blades hydrolyzed approximately one-third of the sucrose fed them. On the later date a slightly smaller portion was hydrolyzed, but the difference in hydrolysis of sucrose with age was not as marked as was the difference in sucrose synthesis. Cane sugar synthesis involves presumably, the transformation of glucose into fructose and the combination of these two sugars. Energy is involved in this synthesis, for it does not occur without oxygen (table 8). The rate of respiration, no doubt, declined with senescence and was probably an important factor in the results (Boysen-Jensen, 1912).

Percentage of water and sucrose synthesis .-Hartt (1937) and the author (Leonard, 1938) have pointed out that the percentage of water in the tissue influences the balance between the reducing sugars and sucrose. Schroeder and Horn (1922), Ahrns (1924), and Schroeder and Herrmann (1931) have shown that in wilting leaves, starch is transformed into sucrose. Schroeder and Herrmann consider that the wilting results first in the hydrolysis of starch to glucose. Glucose is then thought to be partially transformed into fructose and these two sugars combined to form sucrose. Nelson and Auchincloss (1933) and others have shown that drying potato slices at room temperature resulted in an accumulation of sucrose. Apparently potato tubers and leaves are affected in a similar manner by desicca-

Corn leaf blades were gathered at 2:30 p.m., August 12, 1938, and brought directly to the laboratory. Thirty-gram samples were placed on the laboratory benches, and the room was semi-darkened.

Duplicate samples were taken at once and after the periods indicated in table 5. Analysis of the residue showed no dextrin to be present. The data show that there was an increase in the total sugars from 2.06 to 2.50 per cent during the experiment. The increase in total sugars must have been at the expense of some acid-hydrolyzable fraction, since neither dextrin nor starch were present. No fructose was found until the third hour of drying, after which it increased until the end of the experiment. The glucose content of the blades remained almost constant. Sucrose did not show any significant change until the 9th hour of drying, after which it increased by 0.16 per cent.

Medium-aged cabbage leaves were gathered at 3 p.m. November 10, 1938, from plants which had not yet started to head, and were taken at once to the laboratory. The midribs were removed, the blades cut into strips approximately one-half centimeter wide, and samples weighed in triplicate. The latter were held at 34°C. for 18 hours, with and without oxygen. The leaves were tested with IKI and were found to contain starch at the start of the experiment, and one might expect, as others have shown (Schroeder and Herrmann, 1931; etc.), that starch would be hydrolyzed in the drying process. The blades dried at 34°C. increased in total sugars from 1.43 to 2.27 per cent when calculated on the basis of the original green weight of the tissue (table 6). Even with the large increase in total sugars, there was a decrease in reducing sugars from 1.06 to 0.24 per cent. Fructose decreased from 0.44 per cent at the start of the experiment to none at the end. This change is the reverse of that which was observed in corn blades. Glucose decreased from 0.62 to 0.24 per cent during the experiment. Sucrose increased during drying from 0.37 to 2.03 per cent.

The samples placed in nitrogen lost very little moisture. However, it is interesting to observe that

although there was a small increase in total sugars, these blades lost all of the sucrose which they initially contained. Cabbage samples placed in a moist chamber, as will be shown later, lost only a third of their sucrose content. The necessity of oxygen for the synthesis of cane sugar will be considered under a special heading.

Another series was run on cabbage to determine the effect of moisture percentage of the blades on the synthesis of sucrose. The leaves employed in this experiment were gathered on December 19. 1938, and had been hardened by the frequent cool weather. These blades, in contrast to those harvested earlier, contained no starch. Ten-gram samples were taken in triplicate and placed in an incubator at 33±0.5°C. A check series was placed in a desiccator partly filled with water. In these the reducing sugars decreased from 2.93 to 2.41 per cent and sucrose from 0.60 to 0.40 per cent in 21 hours. Changes in the composition of the blades during drying are shown in figure 2. Total sugars, in contrast to the previous series which contained starch, decreased slightly throughout the experiment, a change which was probably ascribable to respiration. At the start of the experiment the reducing sugars were very high and sucrose low in comparison. As the blades lost water, sucrose was

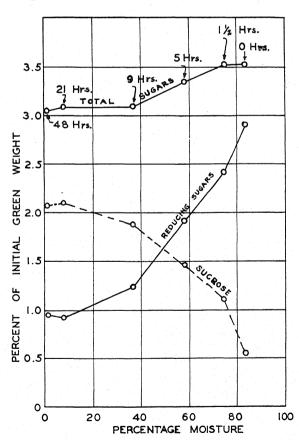

Fig. 2. The effect of drying at 33°C. on the composition of the cabbage blades.

formed from the reducing sugars. It is interesting to observe that the synthesis of sucrose continued until the blades were almost completely dry. The data confirm a previous conclusion by the author (Leonard, 1936) and by Hartt (1936) that the hydration of the tissue affects the relative proportion of the reducing sugars to sucrose. As previously sug-

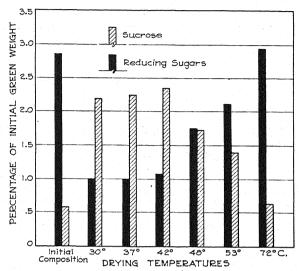

Fig. 3. Sucrose and reducing sugars in cabbage blades before and after being completely dried at different temperatures.

gested (Leonard, 1938), the reducing sugars may be confined to the vacuoles and sucrose to the protoplasm. If on drying, the vacuoles lose proportionately more water than the protoplasm, the reducing sugars will be transformed into sucrose. When leaves which had been dried were rehydrated, complete disarrangement of the protoplasm ensued, as indicated by the fact that the water in which these samples were soaked contained almost all the sugar (now completely inverted) and gave a heavy precipitate with neutral lead acetate. Evidently drying injury is due more to destruction of the protoplasmic membranes than to enzyme changes.

Temperature and sucrose synthesis.—An experiment was conducted to determine the influence of temperature on sucrose synthesis. Cabbage blades were dried at a series of temperatures, and the results are shown in figure 3. It is evident that the synthesis was undisturbed by temperatures of less than 42°C. At 48°C. the synthesis was less than at 42°C., and at 72°C. the tissue dried without change in composition. The rate of drying may have been a factor influencing these results. However, a study of the data in figure 2 reveals that the synthesis of sucrose still continued in cabbage leaf blades at the lower temperatures until they were practically dry. It is interesting to observe that even at the higher temperatures there was no hydrolysis of the cane sugar. Note also that a chemical analysis of air dried

Table 7. Changes in the composition of corn blades fed 6 per cent glucose at different temperatures. Data are percentages of the sugar-free dry weight.

Temperature	Time	Sucrose	Sucrose synthesis per hour	Synthetic efficiency	Glucose	Fructose
Initial composition.	0 hrs.	4.40			1.12	none

cabbage leaves would give an erroneous impression of the carbohydrates of the living leaf.

In a second experiment corn leaf blades were held in 6, 4, and 2 per cent glucose solutions at 50°C., 40°, 30°, and 8°C. The data for the 6 per cent glucose series are shown in table 7. The most synthesis occurred at 50°C. but the greatest efficiency was at 40°C. It is interesting to note that only at 8°C. was there any fructose detectable. Evidently the rate of sucrose synthesis was decreased at the lower temperature, or the equilibria within the tissue changed, to allow some fructose to accumulate.

The synthetic efficiency was greatest with a 2 per cent glucose solution at 50°C., being 98.7. The synthetic efficiency at 40°C. with 4 per cent glucose was only a little less than this, being 98.0. The sucrose synthesized during the experiment was almost equal to the quantity of glucose absorbed, and the corn blades contained very little more glucose at the end of the experiment than at the beginning.

Influence of oxygen and carbon dioxide on sucrose synthesis.—Many years ago Bailey (1906) noted that bananas when dipped in oil or covered with paraffin did not decrease in starch or increase in soluble sugars, while those placed in an atmosphere of hydrogen, illuminating gas, or in a vacuum, increased only a fraction as much in soluble sugars as did those exposed to the air, and lost only a fraction as much starch. Bailey later (1912) showed that ripening bananas left in air lose their starch rapidly through hydrolysis with the formation of sucrose. Boysen Jensen (1912) found that barley and pea seedlings lost some of their sucrose in an atmosphere of hydrogen and regained it again upon being returned to air. He found that the synthesis of sucrose was proportional to respiration, as measured by CO2 production. Cane sugar synthesis ceased with death, but hydrolysis continued. Nelson and Auchincloss (1933) found that slices of Irish potato tubers (Solanum tuberosum) dried in the absence of oxygen formed no sucrose, while slices dried in air accumulated sucrose at the expense of starch. They suggested that the synthesis of sucrose involves aerobic respiration. Rubin and Artsikhovskaya (1937) expressed the belief that the action of invertase in leaves is predominately synthetic or hydrolytic, depending on whether dehydroascorbic or ascorbic acid is present, and thought that this relationship explained the synthesis of sucrose by leaves in an oxygen atmosphere, with hydrolysis in an atmosphere of nitrogen or carbon dioxide.

In our experiments sorghum leaf blades were placed in a nitrogen atmosphere (oxygen removed by pyrogallic acid and NaOH) in 6 per cent glucose solutions for 24 hours. Similar series were placed in carbon dioxide at 30° and 35°C. The data for these are shown in table 8. The blades placed at 35°C. were slightly yellowed at the margin, but those at 30°C. appeared the same at the end as they did at the beginning of the experiment. It is evident that in neither nitrogen nor carbon dioxide was sucrose formed in sorghum blades. In fact, cane sugar underwent some hydrolysis during these tests and there was less at the end than there was at the beginning of the experiment. In table 6 cabbage blades in nitrogen lost all the sucrose which they initially contained. The results of these experiments verify the work of Boysen Jensen (1912) and the conclusion of Rubin and Artsikhovskaya (1937) that sucrose undergoes hydrolysis in nitrogen or carbon dioxide atmospheres. In atmospheres containing oxygen, as has been shown throughout this paper, sorghum readily forms sucrose when supplied with glucose solutions.

Other experiments were conducted to determine whether sorghum blades removed from an atmosphere of CO<sub>2</sub> could continue to synthesize sucrose.

Table 8. Changes in the composition of sorghum blades when fed glucose in  $N_2$  and  $CO_2$  atmospheres at 30°C. for 24 hours. Data are percentages of the sugar-free dry weight.

Treatment	Temp.	Sucrose	Glucose	Fructose	Reducing sugars
Initial composition		3.20	1.46	0.52	1.98
6 per cent glucose, N2 atmosphere	35°C.	1.04	15.97	2.19	18.16
6 per cent glucose, CO2 atmosphere	35°C.	1.88	9.69	1.28	10.97
6 per cent glucose, CO2 atmosphere		2.65	19.37	2.14	21.51

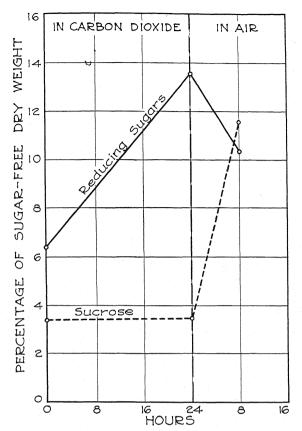

Fig. 4. Changes in the composition of sorghum blades fed 6 per cent glucose in an atmosphere of carbon dioxide and then transferred to air.

The data of figure 4 show that the sorghum leaf blades fed solutions of glucose underwent very little change in sucrose during storage in carbon dioxide. The data of table 8 show that blades stored in nitrogen lost more sucrose during storage than did those stored in carbon dioxide. The difference probably was due to the presence of some oxygen in the latter treatment which was not driven off by the carbon dioxide stream. The data clearly demonstrate that sorghum leaf blades were able to continue synthesis of sucrose after removal from the CO<sub>2</sub> chamber and that the mechanism involved in sucrose synthesis

was not seriously injured by the CO<sub>2</sub>. In this connection, it should be pointed out that the CO<sub>2</sub> contained very little water vapor, as the water was removed by CaCl<sub>2</sub>. No doubt there would have been some CO<sub>2</sub> injury had the gas been high in water vapor (Thornton, 1930).

Evidently leaf blades cannot synthesize sucrose in the absence of oxygen. In an atmosphere of nitrogen or carbon dioxide, hydrolysis, rather than synthesis, seems to prevail. Evidently sucrose synthesis is associated with aerobic respiration, as even in a zero oxygen atmosphere, considerable quantities of CO<sub>2</sub> are produced anaerobically in plants (Steward, 1937).

Iodoacetic acid and synthesis of sucrose.—Iodoacetic acid (ICH<sub>2</sub>COOH) affects certain stages in respiration and behaves as a respiratory poison. In the previous experiments it was found that oxygen was necessary for the synthesis of sucrose and presumably that synthesis is connected with aerobic respiration. Since iodoacetic acid is known to affect respiration, tests were conducted to see if it would influence the synthesis of sucrose.

The following series of concentrations of iodoacetic acid (neutralized with NaOH) were used in the glucose series; 1.0, 0.5, 0.1, 0.01, and 0.001 per cent by weight, and 0.1 and 0.01 per cent in the sucrose series. The concentrations of 1.0, 0.5, and 0.1 per cent iodoacetic acid darkened the leaf blades and seemed to show respiratory injury. Those blades placed in 0.01 per cent solutions appeared normal. The data of table 9 show that there was a loss of sucrose in blades fed 1.0, 0.5, and 0.1 per cent iodoacetic acid, but that at 0.01 per cent and less, synthesis occurred. The sucrose experiments showed a powerful hydrolysis of the sucrose when the blades were fed 0.1 per cent iodoacetic acid in solution with sucrose and still considerable hydrolysis at 0.01 per cent. It is possible that iodoacetic acid affects the synthesis in a manner similar to withholding oxygen. Again it is possible that the accumulation of certain respiratory by-products prevented the synthesis of sucrose by interfering with some stage in the process. Grant (1936) found that 0.02 molar solution of sodium iodoacetate completely inhibited the formation of lactose from glucose in slices of lactating mammary glands.

Table 9. Changes in the composition of sorghum blades when fed 8 per cent glucose solutions containing various concentrations of iodoacetic acid for 28 hours at 34°C. Results calculated as percentages of the sugar-free dry weight.

	Sucrose	Glucose	Fructose	Reducing sugars
Initial composition	4.20	5.78	2.60	8.38
1.0 per cent iodoacetic acid	2.83	28.80	5.00	33.80
0.5 per cent iodoacetic acid	3.18	31.25	5.45	36.70
0.1 per cent iodoacetic acid	3.81	35.03	2.90	37.93
0.01 per cent iodoacetic acid		11.40	3.60	15.00
0.001 per cent iodoacetic acid		6.77	3.33	10.10
Zero		6.80	2.00	8.80

KCN, NaCN, and sucrose synthesis.—Nurmia (1935) noted that additions of KCN to glucose solutions did not affect the synthesis of sucrose within leaves. She thought that since KCN affects respiration, it might also affect synthesis of sucrose. Nurmia used only one concentration of KCN, and this was not given. The writer decided that perhaps there was a critical concentration of cyanide that would be necessary to affect sucrose synthesis.

The first tests were conducted on corn blades using 0.01 and 0.001 per cent KCN. The results were essentially the same as the glucose controls. Since these concentrations were found to be ineffective on corn, the following series was used on sorghum blades: 1.0, 0.5, 0.1, 0.01 per cent NaCN. The data showed approximately the same quantity of sucrose synthesis from glucose with all the cyanide tests, even though those samples placed in 1.0 and 0.5 per cent NaCN solutions were very decidedly discolored. The cyanide solutions were strong with the odor of ammonia.

Another experiment was conducted with the hope of preventing the cyanide to ammonia reaction. A NaH<sub>2</sub>PO<sub>4</sub> buffer was used, and this was adjusted to a pH of 6.4. However, the buffer did not stop the reduction of the cyanide. It was found that KCN in the presence of glucose is changed into ammonia. In the KCN series, none of the concentrations used had any affect on the synthesis of sucrose from glucose. It is possible that the absence of a cyanide effect was due to the reduction of the cyanide to ammonia, either in the glucose solution or in the leaf tissue. It is interesting to note that sorghum blades under natural conditions contain cyanide-yielding compounds, the cyanide often being as high as 0.05 per cent of the green weight (Martin, Couch, and Briese, 1938).

Other experiments.—Other experiments were conducted to determine the effect of KSCN, ether fumes, and invertase on sugar transformations in corn and sorghum leaf blades. No significant influence was noted when feeding sorghum 0.5, 0.1, and 0.01 per cent KSCN with glucose or fructose.

Corn blades in glucose solutions were placed in an incubator containing an open Erlenmeyer flask of ethyl ether. The only observable effect was to increase the fructose fraction of the reducing sugars over the controls.

Various quantities of invertase in glucose solutions were fed to corn and sorghum blades. The lower concentrations of invertase had no influence, while the higher concentrations decreased the absorption of glucose. It is concluded that the colloidal invertase did not penetrate the membranes of the border parenchyma cells. If invertase did penetrate these membranes, it did not influence the synthesis of sucrose nor its hydrolysis, which seems improbable.

Discussion.—Corn leaf blades fed glucose through the transpiration stream increased only slightly in their glucose content but showed a marked increase in sucrose. In the synthesis of su-

crose, glucose should have been partially converted into fructose; yet fructose was not detectable until the fourteenth hour of feeding. If fructose was formed from glucose, it was transformed into sucrose so rapidly as not to be detected. Fructose might thus be formed in photosynthesis and its presence not be shown.

The observation that sucrose can be hydrolyzed to equal parts of fructose and glucose cannot, however, be taken as proof that it is synthesized from the same mixture. It is possible that sucrose was synthesized directly in our experiments from two molecules of glucose or two of fructose and that the appearance of the second hexose within the tissue was the result of sucrose hydrolysis. Sucrose increased markedly within the corn blades, while glucose increased only slightly, even though the latter sugar was the one supplied the samples. It is clear that fluctuations of sucrose within a leaf cannot be taken as proof that that sugar is the first one formed in photosynthesis. Comparable transformations might be expected with other leaf constituents. Hartt (1937) with sugar cane and Warner (1932) with Elodea have come to similar conclusions.

A variety of sugars and sugar alcohols were tested to determine how readily they are transformed into sucrose, and hence into glucose and fructose, in young sorghum and middle-aged cotton leaf blades. Of the materials seldom found in leaves, only galactose was capable of being thus transformed, and then not readily, in sorghum but not in cotton. Apparently, if any of these sugars (mannose, galactose, xylose, arbinose) or sugar alcohols (manitol, dulcitol, sorbitol) was formed in the photosynthetic process, they would accumulate as such. In view of the fact that none of them accumulates during photosynthesis and that they are nearly always absent from leaves, it is clear that they cannot be first products of photosynthesis, but are derived from secondary reactions.

Grant (1936) found that slices of lactating mammary glands when fed glucose, transformed most of the glucose into lactose. He found that active  $\beta$ -galactosidase (lactase) was entirely absent from an acetone-defatted powder of the above glands. He expressed the belief, in opposition to the classical equilibrium theory of the general nature of enzyme synthesis, that lactose could not have been formed by  $\beta$ -galactosidase. In this connection he found a greater synthesis from glucose than from equamolar mixtures of glucose and galactose, while there was almost no synthesis of lactose from galactose alone. These results are strikingly parallel with sucrose synthesis in leaves except that both component hexoses can be utilized. If lactose can be formed in the absence of the active enzyme which hydrolyzes it, sucrose might be similarly formed. Nurmia (1935) found that active invertase was almost if not entirely absent from the blades of the horse bean (Vicia faba), and yet these blades conducted a rapid synthesis of sucrose from glucose or fructose. In a previous paper the author (Leonard, 1938)

noted that synthesis of sucrose was negatively correlated with invertase. Sucrose synthesis was not believed to be due to active invertase, but to occur in conjunction with the protoplasm. It is possible that invertase "bound" with the protoplasm acts in synthesis, while "free" invertase is active in hydrolysis. Under these conditions, invertase would act as the key in the synthetic reaction, the energy being supplied through aerobic respiration. In any case it is becoming increasingly evident that active, hydrolytic enzymes do not necessarily have the powers of synthesis assigned to them by older theories.

Oxygen was found to be necessary for synthesis of sucrose in blades. Sorghum leaf blades fed glucose in nitrogen not only did not synthesize cane sugar, but lost part of the sucrose which they initially contained. Blades held in CO2 produced no sucrose, but when returned to air at the end of twenty-four hours synthesized an abundance of sucrose. Evidently oxygen or aerobic respiration is in some way connected with the synthesis of sucrose. It might be supposed that since a sucrose molecule is at a slightly higher energy level than are two molecules of glucose and fructose and since energy is released upon its hydrolysis, energy must be supplied in its synthesis. Evidently the energy supplied is obtained through aerobic respiration. Iodoacetic acid (ICH2COOH, neutralized with NaOH) reduces sucrose synthesis. Grant (1936) found that a 0.02 molar solution of sodium iodoacetate prevented the synthesis of lactose from glucose. Iodoacetic acid or its salts may interfere with some phase of aerobic respiration which is associated with synthetic reactions.

Drying of leaves, potato tubers, and probably any plant organ at normal temperatures causes the conversion of starch into sugars. In cabbage blades at the start of the drying the reducing sugars were greatly in excess of sucrose, and sucrose was formed at the expense of both reducing sugars and starch. If the reducing sugars and the invertase were in the vacuole while the sucrose synthesizing system was confined to the protoplasm, drying by reducing the relative size of the vacuole might increase the percentage of sugars within the protoplasm. The action of drying on starch hydrolysis is not understood although the observations of Scarth (1932) on reversal of starch hydrolysis in the chloroplasts are suggestive.

The following factors have been studied in their relation to sucrose synthesis: (1) Invertase active in hydrolyzing sucrose seems not to be involved in its synthesis (Nurmia, 1935; Leonard, 1938; and others). This observation is corroborated by the work of Grant (1936) on animal tissue, who found that lactose was formed from glucose in the absence of  $\beta$ -galactosidase in lactating mammary glands. (2) Chlorophyll is not essential. Hartt (1937) was able to demonstrate that albino sugar cane blades could readily synthesize sucrose from glucose. (3) Light is not necessary. Warner (1932), Nurmia

(1935), Hartt (1937), the author (Leonard, 1938), and others have found that leaves and leaf blades fed glucose or fructose in darkness form sucrose readily. (4) Oxygen is necessary. Boysen Jensen (1912), Nelson and Auchineless (1933), and the present work clearly demonstrate the importance of oxygen in the synthesis of sucrose. In the absence of oxygen, sucrose is hydrolyzed rather than synthesized, and sucrose synthesis appears to be associated with aerobic respiration. (5) The quantity of sucrose in a given organ is related to the percentage of water. Cabbage leaf blades synthesized sucrose as they dried, from the reducing sugars present. (6) Sucrose synthesis in drying cabbage blades was prevented by temperatures as high as 72°C. (7) The synthesis of sucrose continues only so long as the cells are alive (Boysen Jensen, 1912), but hydrolysis may continue if invertase is present. (8) Senility of the organ affects synthesis. Cotton blades synthesized sucrose from glucose and fructose less readily when collected late in the season after harvest than when collected before harvest.

#### SUMMARY

A study was made of several factors involved in carbohydrate transformations and in the synthesis of sucrose in corn, sorghum, cotton, and cabbage leaf blades.

Sugar changes similar to those obtained by Loomis (1935) during photosynthesis were obtained by supplying corn leaf blades with 6 per cent glucose. Sucrose increased markedly during the 26-hour feeding period, while glucose and fructose increased only slightly. Hartt (1937) has made similar observations on sugar cane blades.

Glucose, fructose, sucrose, maltose, and lactose solutions fed to sorghum and cotton blades resulted in an abundant accumulation of sucrose. Galactose and cellobiose resulted in a small increase of sucrose in sorghum. Cellobiose, but not galactose resulted in some sucrose synthesis in cotton. There was no synthesis of sucrose from d-mannose, l-xylose, l-arabinose, d-sorbitol, d-manitol, or d-dulcitol.

Sorghum leaf blades fed glucose in carbon dioxide or nitrogen lost rather than gained in sucrose. Cabbage blades left in nitrogen lost by hydrolysis all the sucrose which they initially contained.

Iodoacetic acid (ICH<sub>2</sub>COOH), neutralized with NaOH, at concentrations of 0.1 per cent or higher prevented the synthesis of sucrose from glucose, but not its hydrolysis.

Various strengths of NaCN or KCN, KSCN, ethyl ether fumes, or invertase had little effect on sucrose synthesis.

Drying corn leaf blades resulted in a slight increase in sucrose and fructose. Cabbage blades on drying synthesized large quantities of sucrose from the reducing sugars. This synthesis continued until the blades had a moisture content of 8 per cent, but was prevented by heating at 72°C.

Sucrose synthesis from glucose or fructose decreased with senescence in cotton blades.

Sucrose was synthesized less readily at 8°C. than at higher temperatures (30°-50°C.).

The synthesis of sucrose is an anabolic process requiring energy. The energy necessary is probably derived from certain stages in aerobic respiration.

Active invertase is apparently not involved in this process (Leonard, 1938).

# A NEW SANDBUR FROM WESTERN OKLAHOMA: CENCHRUS ALBERTSONII 1

# H. Everett Runyon

On May 24, 1936, new growth of sandburs (Cenchrus) was observed emerging from the base of perennial plants on pastures near the Cimarron River north of Woodward, Oklahoma. The old burs persisting from the previous year were distinctly different from those produced by the annual, C. pauciflorus Benth., which is the only species of Cenchrus described as occurring in this locality. Similar differences with respect to the burs were observed by the author in 1935 while chartographing native vegetation in northwestern Oklahoma. Plants were transferred to the grass nursery at Hays, Kansas, in 1936 and to the breeding nursery at Woodward, Oklahoma, in 1937 where they were studied intensively during those years.

During the growing season of 1937 plants of this perennial form, Cenchrus albertsonii, were transferred to the nursery. Every month during the winter, two of these plants were transferred to the greenhouse. These plants resumed growth and flowered, also the plants remaining outside resumed growth and flowered.

BRIEF LATIN DESCRIPTION.—Cenchrus albertsonii Runyon, sp. nov., perennis, C. paucifloro annuo similis; culmi tenuiores, foliis angustioribus, spinis paucioribus reflexioribus; spiculae involucri ternae.

Herba condensa, culmis 20-70 cm. longis. Foliorum laminae juventute plicatae, senes aliquid planae, subtus carinatae, 5-15 cm. longae, 3-8 mm. latae. Spicae 4-8 cm. longae. Involucra 10-18 cm. trans spicam, spinis exclusis 3-6 mm. lata et 4-6 mm. longa, pubescentia. Spinae 20-30, extendentes, planae, basibus latiores, mediis curvatis, infimis brevioribus et minus regidis, saepe 5 mm. longis. Spiculae 2-3, saepius tres in utroque involucro.

Appellatus ex Dr. F. W. Albertson, Professore Botanico, Fort Hays Kansas State College, Hays, Kansas, U. S. A.

Description. — Cenchrus albertsonii Runyon. Perennial, resembling plants of the annual C. pauciflorus of the same region, usually the culms more slender, blades narrower, burs less crowded on the spike, the spines on the bur more reflexed. Spikelets usually three per bur, as compared with two in C. pauciflorus. Differs from C. gracillimus in its

<sup>1</sup> Received for publication April 13, 1939.

During the course of this work the author was associated with the Division of Forage Crops and Diseases, Bureau of Plant Industry, Southern Great Plains Field Station, Woodward, Oklahoma.

spreading culms and pubescent burs and from *C. incertus* in having spines covering the body of the bur and in being deeply cleft on the outer surface, exposing the spikelets.

Culms 20-70 cm. long, spreading, ascending or rarely suberect. Often forming dense clumps, freely branching, flattened near the base, scabrous below the spike, internodes glabrous. Blades folded when young, becoming somewhat flattened with age, strongly keeled on the lower surface rough on the upper surface, with a fine white margin. Sheaths mostly shorter than the internodes, margin scarious, loose. Ligule a ring of hairs about 0.5 mm. long. Spikes terminal, numerous, 3-10 cm. long of 10 to 18 burs, the axis flexuous, angled, scabrous, the burs 3-6 mm. wide (excluding the spines), on a peduncle about 2 mm. long, deeply cleft, exposing the spikelets, the spines 20-30, 4-6 mm. long, minutely pubescent, generally reflexed, flat, broadened at the base, the lowermost shorter and more slender. Spikelets 2 or usually 3, 4-7 mm. long, about 2 mm. wide, first glume narrow, reduced, not more than onethird the length of the spikelet, 1-nerved; the second glume slightly shorter than the sterile lemma, sterile lemma and second glume 3- or usually 5-nerved, enclosing the acuminate-pointed fruit.

Loose sandy pastures and roadsides, Harper and Woodward Counties, Oklahoma. Flowers from spring to late fall.

Named in honor of Dr. F. W. Albertson, Professor of Botany, Fort Hays Kansas State College, Hays, Kansas.

This species seems to be confined to a limited area in northwestern Oklahoma. Observations indicate that the plants are capable of withstanding moderate and dry winter but seldom retain life for more than a few years, as the old crowns are not strong as compared to other perennials.

The type specimen No. 200 collected at Woodward, Oklahoma, July 4, 1937, is deposited with the United States National Herbarium, Washington, D. C. Other specimens, No. 201 and 202, have been deposited in the Bartholomew Herbarium, Fort Hays Kansas State College, Hays, Kansas.

Thanks are extended to D. A. Savage, Agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry, for assistance with plants.

# CELL SHAPE STUDIES IN THE PITH OF EUPATORIUM PURPUREUM 1

James W. Marvin

For more than a hundred years the cell has been recognized as the unit of organization of multicellular plants and animals. The structure and functions of cells have been intensively studied, but their shape as they occur aggregated into tissues has received little careful attention since it was first described as polyhedral in the seventeenth century. With the exception of the penetrating investigations by Lewis, no real attempts have been made to determine the three-dimensional form of massed cells. Additional knowledge of the shape of such cells should prove useful in the further evaluation of the factors concerned in shape determination. One hundred pith cells of Eupatorium purpureum L., favorable material because of large and relatively uniform size, were modeled on a large scale. The number of faces on each was then determined, and comparative studies were made of the areas of the faces and of the total surface areas and volumes of the cells. Such investigations add to the very limited precise data on cell shapes, and they also form the basis for an analysis and understanding of the factors underlying cell shape determination.

LITERATURE REVIEW.—As long as the existence of cells has been known, there has been speculation as to their form. Even Hooke (1665) likened the cells of bottle cork to the hexagonal compartments of the honeycomb. Grew (1675) observed that cells from the stem of borage and thistle may be pentagonal, hexagonal, or heptagonal in section, and later (1682), he stated that these "bladders" are often spherical but that in the parenchyma of the bark their shapes are similar to those of the "froth of beer or eggs." Malpighi (1687) also showed figures of parenchymal cells as angular structures.

More than one hundred years later, Sprengel (1802) observed that certain cortical and pith cells were hexagonal in outline, and he suggested economy of space (which he also assigned as the reason for the hexagonal nature of the bee cells) as the explanation. Buffon (1753) had previously considered the shape of the chambers in the honeycomb, using as an analogy the shape of peas which he caused to swell in a glass vessel. Treviranus (1806) and Rudolphi (1807) also recorded the frequently hexagonal outline of parenchymal cells.

Numerous authors have described cells as polyhedra having twelve facets arranged in various patterns. Mirbel (1801) figured the cells in the thallus of *Fucus* as hexagonal in transverse and longitudinal section. The following year (1802) he drew twelvesided parenchymal cells in three dimensions: he illustrated a rhombic dodecahedron and a modifica-

<sup>1</sup> Received for publication April 25, 1939.

For the friendly suggestions, guidance, and valuable criticisms of Professor Edwin B. Matzke, I am deeply grateful. Professor Frederic T. Lewis has also read the manuscript, and his comments and suggestions are sincerely appreciated.

tion of it, an elongated form with four hexagonal and eight quadrilateral faces. He also drew a double hexagonal pyramid. Although Mirbel did not discuss these figures, Bernhardi (1804) accepted the rhombic dodecahedron as one of the shapes assumed by parenchymal cells, and Kieser (1815) stated categorically that this is their form, since spheres compressed in the most economical space-filling arrangement yield this figure. A few years later he reiterated this conclusion (Kieser, 1818), and a consideration of possible shapes, including the pentagonal dodecahedron, left him convinced that the rhombic dodecahedron is the fundamental shape of parenchymal cells; he considered this the figure with the minimum surface which will stack without interstices. He pointed out that a modification of this is commonly achieved—the same modification of the rhombic dodecahedron that Mirbel represented. Kieser's views were accepted by many investigators (Meyen, 1830; Slack, 1832; Schleiden, 1845; Unger, 1846; Oken, 1847; Gray, 1887; McNicoll, 1929; and others). Link (1824), DeCandolle (1827), and Le Maout (1844) accepted Kieser's views with some reservation, since they noted that cells in section are often pentagonal or heptagonal as well as hexagonal. Von Mohl (1852) conservatively cautioned that since cells are usually of unequal size, the rhombic dodecahedron is infrequently realized in cellular tissue. De Jussieu (1852) proposed still another twelve-sided figure, a combination of a tetragonal prism with a tetragonal bipyramid (two tetragonal pyramids placed with their bases on opposite sides of a rectangular prism). He pointed out that in tissues the geometrically regular figure is seldom seen.

Bernhardi (1805) seems to have been the first of the early authors to consider cells fourteen-sided; he rejected the rhombic dodecahedron as a fundamental shape in favor of a truncated form of Mirbel's double hexagonal pyramid. Such a figure has fourteen faces. This was accepted by Kieser (1812) with a reservation, since these figures will not aggregate without interstices, and for this reason he was unable to explain their occurrence in tissues. The next year, as already noted, he changed his views in favor of the rhombic dodecahedron. Turpin (1829) also figured an unstackable fourteen-sided cell, unfortunately without discussing it, and seventy-two years after Bernhardi, Duchartre<sup>2</sup> (1877) proposed another fourteen-sided figure as the fundamental shape of parenchymal cells. This figure, like Bernhardi's, is a double hexagonal pyramid truncated at the ends. Duchartre did not describe the position and nature of the faces with reference to each other, but on the basis of his drawings of cells,

<sup>2</sup> Lewis, in a private communication, has pointed out that the passage referred to here also occurs in the first edition, 1867.

the figure seems to differ from Bernhardi's in the position and length of the lateral faces. A long and a short, apparently rectangular face appear on each side of the hexagonal cylinder alternating in their position around the figure in such a way that trihedral rather than tetrahedral angles occur.

Early investigators attributed the polyhedral form of parenchymal cells to the effect of mutual pressure on spherical structures. The importance of surface tension in such semi-liquid systems was not emphasized until Plateau published his experiments on the statics of liquids in 1873. Berthold (1886), and Errera (1886), applying Plateau's generalities to cellular systems, defined the position and shape of new cell walls, and Roux (1897) found that cleavage patterns in animal eggs were closely simulated in oil droplets. Thompson (1917) has treated extensively the relation of surface tension to cells and cellular tissues. More recently Thomson and Hull (1934) and Welch (1935) have presented Thompson's views on the position of new walls in dividing cells. Wodehouse (1935), in discussing the effect of gravity on symmetry, stated that pollen grains, on which gravitational influence is much reduced, are basically spherical, since surface tension has become much more important as a form determinant. Seifriz (1930), in a paper on the alveolar structure of protoplasm, is of the opinion that the alveoli are rhombic dodecahedra.

Previous to 1887 the rhombic dodecahedron had been considered the most economical surface-volume figure permitting the division of space without interstices. In that year, Lord Kelvin, after experimenting with Plateau's cubic frame, proposed a new fourteen-sided figure. He showed that this figure, which he later (1894) called the orthic tetrakaidecahedron, with its eight hexagonal and six square faces, dihedral and trihedral but no tetrahedral angles, is more stable than the rhombic dodecahedron, and (according to Lewis, 1925) it is also more economical in its surface-volume relationships. The orthic tetrakaidecahedron is not unknown to the crystallographers, for it was described by Romé de l'Isle (1783) as a truncated regular octahedron, by Mallard (1879), and by Tutton (1911), among others, as one of Von Fedorow's five parallelohedra, a cube truncated by an octahedron. Although he is not the first to suggest it, Baitsell (1937) emphasizes the crystalline structure of protoplasm, and he thinks that death is a crystalline pattern permanently set. Wrinch (1937) concludes that protein molecules are fundamentally hexagonal in shape and that the wide range in the number of types of proteins results from combinations of this pattern.

Matzke (1927) has shown that orthic tetrakai-decahedra of uniform size will aggregate to fill space completely. He has also described a simple method for the construction of accurate models of this figure (1931). Models, constructed by this method, were stacked (Marvin, 1936) and a formula developed to express the aggregation series. Recently Glaser and Child (1937) suggested a relation between the or-

thic tetrakaidecahedron aggregation series and animal growth by substituting this series for one of the variables in Huxley's relative growth formula. although, in another paper (1938), Glaser points out that the implications of this relationship are not clearly understood and it may be fortuitous. Hancock (1938) derived mathematically a fourteensided figure having eight triangular and six square faces with twelve vertices at each of which four faces meet at a point. Thompson (1917) was impressed with the fact that spheres of uniform size when most compactly arranged yield rhombic dodecahedra upon compression. He says that orthic tetrakaidecahedra could be realized if the walls of the spheres or cells were perfectly elastic. He thinks, however, that since cell walls are not perfectly elastic, the fundamental shape of parenchymal cells probably is the rhombic dodecahedron.

There appeared in 1923 the first of a remarkable series of studies by Lewis on the three-dimensional shape of cells. In the first paper (1923), 63 cells of elder pith were modeled from serial sections, and they had an average of 13.96 faces. Examination of 37 additional cells did not change the average. After careful study, Lewis became convinced that these cells approximated orthic tetrakaidecahedra, although he did not observe such a figure. Pentagonal faces were relatively common in addition to the hexagonal and quadrilateral faces expected. He suggests that differences in the volumes of adjacent cells might well cause the appearance of two pentagonal faces instead of the expected quadrilaterals or hexagons. The modifying effect of cell division is also considered by Lewis to be an important factor in inducing the observed irregularities. The possible effect of division on the shape of a dividing cell is discussed in detail. Lewis (1925), continuing these studies, examined 100 stellate cells of Juncus, 100 human adipose tissue cells, and 50 stratified oral epithelial cells. As in the elder pith studies, he concluded that fundamentally they are derived from the orthic tetrakaidecahedron. In another paper (1928a), the columnar epidermal cells of cucumber were found to be essentially hexagonal prisms, but with four basal contacts and one exposed surface, making eleven faces in all. He extended this study (1930) in a discussion of the effect of growth and division on the shape of these cells. A discussion of the properties of a mosaic of polygons (Lewis, 1931) and of epidermal mosaics (Lewis, 1933a) was followed by a general discussion of cell shape (Lewis, 1933b). From a study of models (1935) he showed that the tracheids of pine may also be derived from the orthic tetrakaidecahedron, although in development additional contacts occur, increasing the number to twenty or more for a mature cell.

Gray (1931) has discussed the work of Thompson, Lewis, Matzke, and others on cell shape, and he emphasizes the fundamentally biological nature of the problem. Hein (1930) sectioned the pseudoparenchyma from the sclerotia of an ascomycete in three planes at right angles to each other and found

that the cells were essentially isodiametric and hexagonal in outline. From this he concluded that they are tetrakaidecahedra and that the orthic tetrakaidecahedron is their fundamental shape.

Lewis' studies were in the main on mature tissue. Tupper-Carey and Priestley (1924), in an investigation of meristematic tissue, macerated cells from the apical meristem of a Vicia faba root. These were polyhedra, and the authors believed them to be fourteen-sided, although counts of the numbers of faces on individual cells were not made. Priestley (1928, 1929), discussing the nature of meristematic cells, emphasized the effect of internal pressure on the form of these plastic cells, and he concluded that they approach "the shape of the dodecahedron or tetrakaidecahedron." He has also considered the question of sliding growth as it may affect the form of meristematic cells (1930). An alternative hypothesis is advanced whereby cells might change their position with reference to adjacent ones without assuming a movement of one wall over the surface of an adjacent cell. This change in the relative position might be accomplished, he suggests, by a gradual mutual adjustment of the cells as a "common framework."

Gane (1930) described a method for simulating the shape of meristematic cells: plasticine balls were compressed so as to eliminate all the spaces between them. He found that when they were stacked so that twelve balls were in contact with a central one, fourteen and not twelve faces were formed. This is not in agreement with recent work on lead shot (Marvin, 1937, 1939) in which lead balls of uniform diameter were stacked in a cylinder in such a fashion that, except for the peripheral layers, twelve shot were in contact with a central one, and after compression, dodecahedra were formed. If the shot were poured at random into the cylinder and compressed, the average number of contacts was fourteen (14.17). The formation of rhombic dodecahedra or orthic tetrakaidecahedra by compression of spheres depends upon arrangement and uniformity of size.

Matzke (1939) has recently demonstrated the controlling effect of size differences on the shape of compressed spheres and its importance in cell shape determination. He compressed lead spheres of two diameters, one twice that of the other. When these shot were mixed in differing proportions, the average number of faces on the small spheres varied from 9.5 to 13.3, while the large shot had anywhere from 19.98 to 30.18 as the average number of contacts. The small shot always had fewer than fourteen contacts and the large shot more than fourteen. Correlated with these changes in the number of faces was a change in the occurrence of the kinds of faces. An average of fourteen contacts can be predicted, therefore, only when the compressed spheres are of uniform size or are in certain definite proportions.

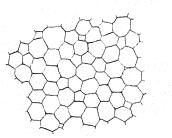

Method.—Stems of Eupatorium purpureum L. were collected in the vicinity of New York City August 9, 1937. The plants were entering the flowering

period, and there was very little vegetative growth. The pith cells from the upper quarter of the stem were large, approximately isodiametric or slightly elongated, and the intercellular spaces were small and infrequent. Hand sections of the stem made possible the selection of portions in which the pith was approximately twenty-five cells in diameter, a ratio not uncommon in stems, and approaching the ratio used in the study of compressed lead spheres in previous investigations by Matzke (1939) and Marvin (1939). Models of 100 cells from these selected sections were constructed by the method previously described (Marvin and Matzke, 1939).

The first 50 cells were taken from the more peripheral part of the pith, although the several outermost layers of pith cells were not used at all. The 25 cells modeled first were selected at random, whereas cells 26–50 were taken from a small group removed en masse. Cells 51–100 were from a fragment of the central portion of the pith.

The camera lucida drawings of the faces of the cells from which the models were constructed were made at a magnification of 170 diameters. Surface areas of the faces and of the models were measured on the camera lucida drawings with a planimeter. The models were water-proofed with a cellulose acetate preparation and their volume obtained by suspending them in distilled water from one arm of a torsion balance. To the lifting power of each its weight in air was added, thus giving the weight in grams of water and consequently the volume in cc. of the model.

Data.—Text figures 1 and 2 illustrate the appearance of the pith cells studied in transverse and longitudinal section respectively. In figure 1 the cells appear essentially isodiametric, although they vary somewhat in cross-sectional area and show 4–8 contacts. No tetrahedral angles are present in this view, and the few intercellular spaces are small triangular areas. In longitudinal section the cells have a different appearance (fig. 2). In this figure they are oriented in rows which correspond to the vertical rows in the plant (fig. 2, A, B, C, D, E, F, and G). The members of some rows are elongated (A and D), while in adjacent rows the cells are isodiametric or even flattened (fig. 2, B and C). The elongated cells have their long axes parallel to the long axis of

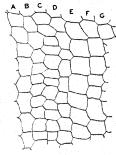

Fig. 1-2.—Fig. 1 (left). Transverse section through pith of *Eupatorium purpureum* L.—Fig. 2 (right). Longitudinal section through same. ×46.

the stem. From this view we see that the cells commonly have one upper and one lower contact. There are frequently two lateral contacts on each side for the elongated cells and one or two for the shorter ones. These lateral contacts are frequently asymmetrically placed with reference to the midpoint of the length of the cell. The transverse view gives an approximation of the number of sides, each of which may consist of one or more faces. The average number of contacts on the cells shown in figures 1 and 2 may be computed by a method developed by Lewis (1928b), similar to Duchartre's approach. There are fifty-five cells shown in transverse section in figure 1 with a total of 330 edges. They thus have an average of 6.0 sides. In longitudinal section, as seen in figure 2, in addition to top and basal contacts, from one to four lateral contacts occur. By actual count there are 108 sides with 219 lateral contacts, or an average of 2.03 lateral contacts per cell. Assuming that the transverse and longitudinal sections are typical, an average cell would have six sides with 2.03 faces on a side or 12.18 facets. Two additional contacts, one at the top and one at the base of the cell, upper and lower contacts in figure 2, increase the average to 14.18. Such an average if based on large numbers is a useful check on the more accurate study of models of individual cells.

The variations in size and form of the 100 cells modeled are shown in plates I and II, figures 1–100, which correspond to cells 1–100 in table 1. These are photographs of the models of the cells somewhat reduced in size and numbered from 1–100 in the order studied. Considerable variation in size is apparent. The model of the smallest cell, number 80, has a volume of 1.5 cc., while that of number 73, the largest, is 22.5 cc. Great diversity of form is also apparent. Cell models 53, 62, 65, 76, and 83 appear as fundamentally several-sided prisms with one or sometimes two faces on each side. This pattern, less clearly seen in many other cells, seems entirely lacking, for instance, in number 40.

The numerical data are given in detail in table I and in summary form in tables 2, 3, and 4. In table I the frequency of occurrence of each kind of face is recorded for each cell and also the total areas of each kind of face on the model. The total number of faces, the total area of the faces as measured in square inches and computed in square centimeters,

and the volume of each model are also given. In addition, the surface area of a sphere having a volume equal to the observed volume of the model was computed. Lewis (1925) has published the results of Graustein's computations in which the surface of a rhombic dodecahedron is given as 1.1050 times the surface of a sphere of equal volume, and the surface of an orthic tetrakaidecahedron is given as 1.0987 times that of a sphere of equal volume. These values were used in computing the surface areas of rhombic dodecahedra and orthic tetrakaidecahedra with volumes equal to the volume of each cell model. Thus, model number 1 has five quadrilateral faces with a combined surface area of 0.62 sq. in., two pentagonal faces whose areas equal 0.74 sq. in., and six hexagonal faces with a total area of 2.55 sq. in. The model was thirteen-sided with a total surface area of 3.91 sq. in. or 25.22 sq. cm.; its volume was 9.30 cc. A sphere of this volume has a surface area of 21.24 sq. cm., and an orthic tetrakaidecahedron and a rhombic dodecahedron of the same volume, 9.30 cc., have surface areas of 23.34 sq. cm. and 23.47 sq. cm., respectively. The sphere is the most economical surface-volume configuration, and in this series the orthic tetrakaidecahedron comes next, the rhombic dodecahedron third, with the cell model slightly less economical than the rhombic dodecahedron. At the bottom of the table appear totals of the number and the areas of each kind of face as well as the total number of faces on the 100 cells; the total area and volume of the cell models and the total computed areas of the spheres, orthic tetrakaidecahedra, and rhombic dodecahedra are also given.

The distribution of the number of contacts observed on the 100 cells is shown in table 2. The number of sides ranges from seven to twenty with no eight-sided cells observed. This is similar to Lewis' (1923) results in a study of elder pith cells in which he observed a range from 6- to 20-sided cells which included no nine-sided ones. He found 21 cells having 13 sides, the group of greatest frequency, 19 fifteen-sided, 16 fourteen-sided ones, 10 with 16 sides, and 8 each of 11- and 12-sided cells. In the present study, 12-sided cells are most common, 18 in all; those having 14 and 15 sides are next most common with 15 of each; and there are fourteen 13-sided cells, and 13 which have 11 sides. While there were more 12-sided cells than any other

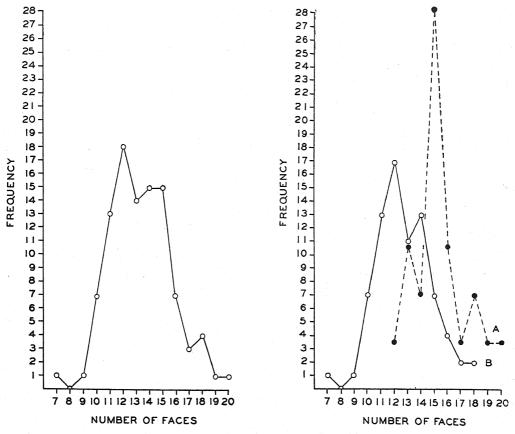

Fig. 3-4.—Fig. 3 (left). Frequency curve showing the distribution of the number of contacts per cell for the 100 cells studied.—Fig. 4 (right). Frequency curves showing the distribution of the number of contacts per cell on the 100 cells divided into two groups according to volume; curve B represents the small cells, and curve A the large cells.

kind, it is obvious that there was no polyhedron that was much more abundant than all the others. The maxima were in the range from 11- to 15-sided cells, with none markedly predominating. Thus the data on the frequency of occurrence of the number of faces observed on the *Eupatorium* pith cells show marked similarity to those recorded by Lewis for 100 pith cells. The data given in table 2A are presented graphically in text figure 3. No well-defined mode is apparent, although 12 is clearly the group of greatest frequency.

The 100 cells studied were then divided arbitrarily into two groups according to the volumes of their models (table 2, B and C): the volume of the smallest cell model is 1.5 cc. and of the largest, 22.5 cc.; accordingly, all the cells whose models have volumes of 12.0 cc. or less were grouped together, and those with volumes of more than 12 cc. were placed in a second group. Of the 100 cell models, 78 are in the first (12 cc. or less in volume) and 22 are in the second group (more than 12 cc. in volume). A distribution curve of the number of faces on the cells was plotted for each group (text figure 4). To make the curves comparable, each value for the cells having models with volumes of more than 12 cc. was multiplied by 78/22. The group of small cells has

a range of 12, from 7- to 18-sided with the 12-sided ones most common, 17 in number. The larger cells show a range of 9, from those with 12 to those with 20 faces, and the 15-sided ones, of which there are 8, are most common. It is apparent here that when the cells are divided into two groups according to the volumes of their models, a distribution curve for each shows a well-defined modal class which also rather closely approximates the average for each group. The 78 smaller cells average 12.78 contacts and the 22 larger ones 15.41 contacts. By contrast, the graphical treatment of the 100 cells as a unit (text figure 3) shows no pronounced modal class, and the group of greatest frequency, 12, does not represent the numerical mean, 13.36. This indication of groups in the population is important and agrees closely with lead shot data previously obtained (Matzke, 1939).

The division into two groups is distinctly arbitrary, and the cells may also be divided into groups depending upon the number of faces. Thus from table 1 it is possible to calculate that there are 7 cell models having 10 faces and an average volume of 4.98 cu. cm.; there are 13 models with 11 faces and an average volume of 6.48 cu. cm.; there are 18 models with 12 faces and an average volume of 7.90

Ratio	.04	4.18	4.71	3.63	.71	.07	.02
Approximate ratio	0	4	5	4	1	0	0

In table 3 the frequency of occurrence of the kinds of faces on the cells studied, a ratio expressing their proportionate occurrence, and also an approximate ratio to the nearest whole number are given. Pentagonal faces occur most frequently with quadrilaterals and hexagons next most common. On the basis of these frequencies, an hypothetical average cell would have 5 pentagonal faces, 4 each of quadrilateral and hexagonal faces, and 1 heptagonal face. No such cell occurred among the 100 studied, although there is no a priori reason why it might not be found.

The frequency of occurrence of each kind of face is given again in table 4, and in addition, the total surface area of each kind of face as measured on the models and the average surface area as derived from these totals. The average areas in square inches were converted to square centimeters, and from these data the average surface area of each kind of face occurring on the cells themselves was calculated. It is apparent that there is a direct correlation between the number of edges on a face and the

size of the face-that is, that the larger faces have more edges than the small ones. Thus, triangular faces have the smallest average area, and those with the greatest average area have the most edgesnamely, 9. The last column of table 4 shows the comparable areas of similar regular polygons. The length of a side for each of these regular figures is 1, since the regular hexagon, whose area was arbitrarily taken as 2.6 units, has unity for the length of each side. A factor for each of the regular figuresfor example, triangle, 0.4; square, 1.0; pentagon, 1.7; etc.—multiplied by the square of the length of a side gives the areas as recorded in the table. These areas and those of the corresponding cell faces are strikingly similar. Such relationships and their significance in epithelial tissue have been discussed by Lewis (1931).

A summary of the total and average number of faces on the cells, the total surface areas and volumes of the models and of the cells, and the surface areas of a sphere, an orthic tetrakaidecahedron, and a rhombic dodecahedron with volumes equal to the volume of the average model and of the average cell are given in table 5. The total number of faces on the 100 cells studied is 1,336 with an average of 13.36 faces per cell. The 100 pith cells studied by Lewis averaged 13.96 contacts. The total surface area of the cell models studied here is 2,465.35 sq. cm. Thus, an average model would have a surface area of 24.65 sq. cm., and by computation, since the models were drawn at a magnification of 170 diameters, an average cell would have a surface area of 85,294.12 sq. microns. It is interesting to note that this value (85,294.12) is not markedly different from the surface area of an orthic tetrakaidecahedron (82,006.92) or rhombic dodecahedron (82,525.96) of equal volume. The sum of the vol-

Table 4. The total numbers of different kinds of faces on 100 cells, their total and average areas as measured on the models in square inches and computed in square centimeters, and the computed average areas in square microns of the different kinds of faces on the cells themselves, and areas of comparable regular polygons.

umes of the models is 972.85 cc. with the average at 9.73 cc. By computation, the average cell would thus have a volume of 1,980,460 cu. microns.

The number of trihedral and tetrahedral angles was recorded: there are 6,732 trihedral angles and 14 tetrahedral angles on the 100 cells, or approximately 1 tetrahedral angle to 481 trihedral angles. In the cells, tetrahedral angles are much less common than in compressed lead shot of uniform diameter in which the proportion of tetrahedral to trihedral angles was 1 to 93. Matzke (1939) studied compressed lead shot of two different diameters mixed in varying proportions, and he found a ratio of 1 tetrahedral angle to every 251 trihedral angles, a result much closer to that found in cells than was obtained for compressed lead shot of uniform diameter. In addition, he found a correlation between the number of tetrahedral angles and the size of the faces in shot: small faces had more tetrahedral angles than large ones. This would be expected if the number of tetrahedral angles were determined merely by space relationships. The faces on the cells are relatively minute, and the fact that tetrahedral angles are much less common here than in compressed lead shot seems to indicate that surface tension has an influence on the position of the cell walls with reference to one another.

Plates III and IV are drawings of models, each of which is shown in three different views, selected to illustrate some of the variations in the shape, size, and arrangement of the faces. Cell number 20 (plate III, figures 20 a, b, and c, and table 1, number 20) is of interest not only because of the arrangement of the faces, but also because it is the only cell observed on which there are no pentagonal faces. It has a total of eleven faces, six quadrilateral and five hexagonal. The quadrilaterals are smaller than the hexagons and have a combined area almost

precisely half that of the latter. The faces are symmetrically arranged. The top, base, and three of the sides are hexagons. Alternating with these three sides are three others each of which has two quadrilateral faces. On two of these last-named sides one of the quadrilaterals is longer than the other, while they are approximately equal in size on the third side. Professor Lewis has suggested that cell number 20 may be derived from the orthic tetrakaidecahedron as follows: "the vertical division of two neighboring cells in contact with two adjacent lateral hexagonal facets converts the 14-hedron into a 16-hedron with heptagonal facets above and below. A vertical division through these heptagonal facets (somewhat unequal, but such as often occurs) produces a daughter cell which is hexagonal on its top and base (the other daughter cell is pentagonal above and below). A horizontal division through the middle of the hexagonal daughter cell gives rise to the pattern in question (in one of its halves)."

Cell 81 (plate IV, fig. 81a, b, c) has thirteen faces of which two are quadrilateral, eight pentagonal, and three hexagonal, thus showing to a marked degree the tendency in the group as a whole toward a predominance of pentagonal faces. The average for the 100 cells shows more quadrilateral than hexagonal faces, while in this case, the reverse is true. As in cell 20, the quadrilateral faces have the smallest average size. The pentagons are next largest (there were no 5-sided faces on cell 20) and, again as in number 20, the hexagonal faces are the largest. In this same cell the top and base are hexagons (81a, b), three of the sides have two pentagonal faces each (81b), two have both a quadrilateral and a pentagonal face (81a, c), and one side is a hexagonal face which appears at the top in figure 81c. In this one cell there occurs in succession a series of faces which show a progressive size increase, espe-

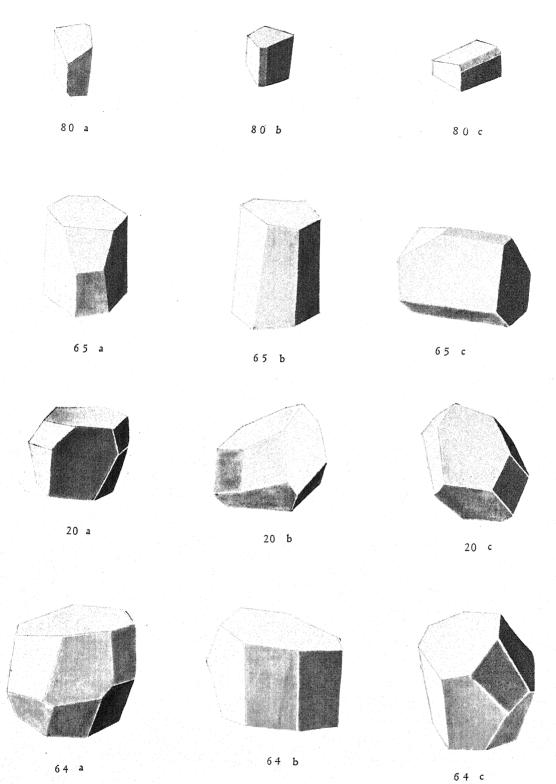

Plate III. Drawings of four different cell models, each in three views, numbered to correspond with their photograps in plates I and II.  $\times 170$ .

cially in proportion to the length of the side of the cell which they occupy. There are no tetrahedral angles on the cell, but trihedral angles are formed between each group of three faces. Cell 81 may be interpreted as a vertically bisected orthic tetrakaidecahedron; two adjacent cells also divided vertically, thereby introducing two additional facets to give cell 81 a total of thirteen contacts.

Cell 100, with 15 faces, of all the cells studied, most closely approximates the orthic tetrakaidecahedron. It has eight hexagonal, five quadrilateral, and two pentagonal faces. Two of the hexagons form the top and the base (only one of these is visible in the drawings, and it appears at the extreme left in figures 100a, b, and c); three adjacent sides (two of these visible in 100b) each have a quadrilateral and a hexagonal face in such a position that the quadrilaterals and hexagons alternate; a fourth side, in addition to a hexagonal and a quadrilateral face, has a small quadrilateral face (upper left-hand corner, 100c); the remaining two sides, each of which is adjacent to the side having the small quadrilateral, have a hexagonal and a pentagonal face apiece. If the small quadrilateral face were not present, the two pentagonal faces would automatically become quadrilaterals, and the number and arrangement of the quadrilaterals and hexagons would be identical with that of Lord Kelvin's figure. Except for this small face, then, this cell approaches the tetrakaidecahedron very closely, although even with the omission of the small quadrilateral it still would not be perfectly regular. The

quadrilaterals on this cell have a smaller average surface than the pentagons, which, in turn, have less surface than the hexagonal faces.

These three cells (20, 81, 100) illustrate the correlation between the size of the faces and the number of edges on a face. They show some of the facesize variations, and they also demonstrate the fact that when two faces occur on one side of a cell, one of them is usually smaller than the other, thereby placing the common edge to one side of the center of the cell. It can also be seen that, while patterns do occur, they are subject to considerable variation.

An analysis of the occurrence of the different kinds of faces found on the cells shows that in many cases two or more cells with an equal number of sides have not only the same kinds of faces but also like numbers of each kind. All of these were collected in table 6 where the combination of number and kind of face as well as the frequency of occurrence of these combinations is recorded. The faces are quadrilateral, pentagonal, and hexagonal, with a few heptagonal. Thus, there are two cells having two quadrilateral, eight pentagonal, and two hexagonal faces; there are two cells having three quadrilateral. six pentagonal, and five hexagonal faces, etc. There are twelve cases in which the same combination of faces occurs twice, eleven where it occurs three times, and in one case the same combination occurs six times. It is evident from the table that since there are twenty-four different combinations, no one can be said to be predominant, although it is rather striking that there are six cells with four quadrilateral, four pentagonal, and three hexagonal faces. A bisected orthic tetrakaidecahedron also has four quadrilateral, four pentagonal, and three hexagonal faces. The arrangements of these faces in the cells and in the bisected models, however, are not the same, and variation occurs between the individual

A further analysis of table 6 indicates that pentagonal faces predominate when the number of quadrilaterals and hexagons is small, and conversely, that when the quadrilateral and hexagonal faces are present in greater numbers, there are fewer pentagons.

Discussion and conclusions.—The 100 cells of Eupatorium purpureum L. pith isolated and studied have an average of 13.36 contacts. This average approaches an average (13.97) obtained by Lewis (1923, 1925, 1933) in a study of 100 elder pith cells, 100 human fat cells, and 50 precartilage cells of the tadpole, all essentially undifferentiated tissues. The range in the number of contacts, 7–20, observed in Eupatorium pith is almost identical with the range obtained by Lewis for 100 elder pith cells.

Studies of the effect of contact and pressure on lead spheres have demonstrated that while spheres of uniform diameter have an average of 14 (14.17) contacts when compressed to eliminate all the spaces, spheres of two different diameters, one twice the other, when mixed together and compressed give averages in which the small shot always have fewer than 14 contacts and the large shot more than 14.

In this same series of experiments, varying the proportion of small shot to large changed the average number of contacts for each group. Thus the small shot averaged 9.5 contacts when there were relatively fewer small shot in the mixture, and the average rose to 13.3 contacts when the proportion was relatively high. The average for the large shot was 19.98 faces when there were more large than small shot by volume and rose to an average of 30.18 contacts when there were more small than large shot by volume. The cells, divided into two groups according to volume, show averages of 12.78 contacts for the small cells and 15.41 for the large ones. As in the lead shot, the small cells have fewer than 14 contacts, while the large ones have more than 14. The marked differences observed in shot would not be expected here since the diameter ratio of small cells to large ones (computed on a basis of spheres for comparison) was 1 to 1.26, considerably less than the diameter ratio of 1 to 2 used in the lead shot study, and the mean diameters of the cell models, 2.48 cm. and 3.12 cm., are based in each case on a considerable range in the diameters of the individuals. However, the correlation between cell size and the average number of faces in a population of cells of different sizes, on the one hand, and the effect of contact and pressure on spheres of two diameters, on the other, is apparent.

Harper (1918a, 1918b), in a consideration of the morphogenetic factors involved in shape determination in certain algae, discussed the effect of contact and pressure on cells whose primary form was determined by surface tension. In the lead shot, surface tension is reduced to a minimum, and distortion from a spherical form is induced by external pressure. In pith the polyhedral cells do not normally develop from spheres; nevertheless the similarity to forms produced by distortion is striking. Harper (1918b) has also emphasized functional hypertrophy as a stimulus in cell form determination, and Priestley (1928) is of the opinion that internal pressure is the force responsible for the polyhedral form of meristematic cells.

The Eupatorium pith cells frequently appear oriented in rows parallel to the long axis of the stem. They are often elongated, and since divisions are commonly transverse, cell division does not change the number of rows of cells. In longitudinal section they appear as in figure 2. Certain of these cells may be looked upon as short or elongated modified prisms each with a single face at top and bottom and with 4 to 8 sides any one of which may consist of more than a single face (fig. 1, 2). Plates III and IV show drawings of eight cell models, each in three views, which have been selected to show several modifications of an essentially prismatic form.

Figures 80a, b, and c (plate III) give three different views of cell number 80, which is an irregular pentagonal prism. There are two pentagonal faces which form the top and base and five quadrilateral faces forming the sides of the figure. This cell might arise from the transverse division of a vertically bisected orthic tetrakaidecahedron if the plane of the

transverse division were one-third of the distance from top to base. Figures 65a, b, and c show that cell 65 is hexagonal in cross-section, has three quadrilateral and two pentagonal faces extending from the top to the base, and a sixth side consisting of two quadrilateral faces, each of which was a contact of an adjacent cell. Cell 20 also has a hexagonal face at the top and base, three lateral hexagonal faces extending from top to bottom, and three other sides, each divided into two quadrilaterals. Thus each hexagonal face alternates with two quadrilateral faces. In cell 64 (fig. 64b and c) there are two quadrilateral and two pentagonal faces extending the length of the cell. The other three sides (fig. 64a) are each divided into two faces. These lateral faces may be narrow and extend a short way along the cell, or they may extend to a point more nearly equidistant from the top and base. Such variations are shown in cell 81 (plate IV, fig. 81a, b, c). Not uncommonly three lateral faces occur on one side of a cell, and Lewis (1923) has pointed out that "this happens whenever, in an aggregation of orthic tetrakaidecahedra, a cell adjacent to a lateral hexagonal facet divides transversely through the middle." In such an event one or sometimes two of these faces are rather small (plate IV, fig. 51a, 100c). Cell 100, previously described, approaches the orthic tetrakaidecahedron in shape. Figures 100a and b show the necessary alternation of quadrilaterals and hexagons. On figure 100c, however, a narrow quadrilateral face appearing at the upper left increases the number of faces to fifteen and changes two of the quadrilaterals to pentagons, thus destroying the orthic tetrakaidecahedral pattern. The greatest number of faces observed occur on cell 57 which has 20. Its model with a volume of 22.3 cc. is within 0.2 cc. of the volume of the largest cell studied, number 73, which is 15-sided.

From plates III and IV it is evident that the size and position of the faces are subject to great variation. The delicate curvatures which some of the faces originally had could not be modeled. In surface tension systems the curvatures are important from the standpoint of stability of angles. Only rarely are four adjacent faces so arranged that a tetrahedral angle is formed. In all the 100 cells there are only 14 tetrahedral angles, while trihedral angles number 6,732. Two of these tetrahedral angles are shown in plate II, figures 60 and 84, and two others in plate I, figures 6 and 30. As has already been pointed out, these angles are much less frequent here than on compressed lead shot of uniform or of different sizes in which surface tension probably plays little or no part. In cells, the operation of surface tension and biological factors would reduce the occurrence of this type of angle. As seen in section, the cells "break joints," and from the models it is apparent that two cells forming one side of an adjacent cell usually have their end walls toward one end rather than in the middle of that adjacent cell. It has already been mentioned in connection with cell 81 (plate IV) that this position varies.

In discussing table 3 it was pointed out that pentagonal faces occurred most frequently with quadrilateral and hexagonal faces next. This is also apparent from plates I, II, III, IV, and table 1. This predominance of pentagonal faces was observed in the studies of compressed lead shot of uniform and of different diameters under most conditions. In the studies on shot of different diameters, the small shot showed more pentagonal faces than any other kind. Lewis (1923, 1925) has pointed out that in elder pith two pentagonal faces frequently occur together. He suggested that this arrangement may represent a modification of the regular alternation of quadrilateral and hexagonal faces found on the orthic tetrakaidecahedron and that greater economy of surface may thus be obtained.

A study of cells of equal volume shows that while cells of the same volume may have the same number of faces, they frequently do not. The considerable range in cell volumes evident from table 1 has already been discussed in the light of its effect on the number of faces; small cells usually have fewer faces than large ones. The surface areas of the cells are also affected by their volumes: small cells have less surface than large ones. A comparison of individuals, both large and small, with regular polyhedra of equal volume shows that the small cells frequently are as economical surface-volume figures as the large cells, and in some cases they are more economical. There are seven small cells (table 1, nos. 36, 59, 71, 72, 86, 87, 90) which are more economical and three (table 1, nos. 30, 56, 80) which are as economical surface-volume figures as orthic tetrakaidecahedra of equal volume. In addition, there are four other small cells which show more economy of surface than rhombic dodecahedra of the same volume. Of the large cells, four (table 1, nos. 4, 17, 39, 58) are more economical than orthic tetrakaidecahedra and two others (table 1, nos. 26, 41) are more economical than rhombic dodecahedra of equal volume. The other 80 cells in the 100 studied have surface areas that are greater than those of either an orthic tetrakaidecahedron or a rhombic dodecahedron of equal volume. However, the differences are often small and possibly no greater than the experimental error. Too much weight, therefore, should not be put on the individual figures. But it may be concluded that both large and small cells can be as economical surface-volume figures as orthic tetrakaidecahedra of equal volume and that in this study no direct generalization between large and small cells can be made in this respect. The striking result of the volume studies is that the cells approach the economical surface-volume relationships of the regular figure so closely. This would indicate that surface tension is important in cell shape determination.

In spite of the differences in materials and methods, the average number of contacts observed for the *Eupatorium* pith cells is rather close to that obtained by Lewis for 100 elder pith cells. Pentagonal faces were most common in the elder pith and are

the most common kind of face (471 in all) observed on the cells studied here. However, quadrilaterals and hexagons are also numerous (418 of the former and 363 of the latter), and the heptagons number 71. In contrast there are only 7 octagons, 4 triangles, and 2 faces with nine edges. While no one kind of face is strongly predominant, the majority definitely occur as three types, faces with 4, 5, and 6 edges, with a fourth type, 7-edged, less frequent.

An examination of the photographs of the cell models (plate I, II) does not reveal a uniformity of pattern, although their shapes may often be interpreted as a modification of the orthic tetrakaidecahedron as shown above. In addition to differences in shape, variation in the kind and number of each kind of face is evident. A study of table 1, however, shows that there are cells which have not only the same kinds of faces but also precisely the same number of faces and of each kind of face-for example, cells 50 and 77 both are 10-sided with two quadrilateral and eight pentagonal faces. In the other twentythree cases (table 6) in which the cells have the same numbers of faces of the same kind, the arrangement of the faces may or may not be similar. It is interesting to note that in twelve of these twentyfour cases similar combinations appear only twice, in eleven cases three times, and in one case six times. This last case comprises 11-sided cells with four quadrilateral, four pentagonal, and three hexagonal faces, all polygons of frequent occurrence. The fact that twenty-four different combinations occur in the 100 cells seems to preclude the possibility that any one pattern is representative of the cells as a group. Although the orthic tetrakaidecahedron may well occur in cells, such a typical figure was not observed here, and these data indicate that it does not occur more frequently than other combinations of faces.

Cell division and cell expansion among the biological factors have a marked effect on cell shape determination. However, some aspects of shape determination can be studied in systems in which these factors are not operative. Thus, lead spheres of equal volume compressed to eliminate interstices averaged 14 faces of which pentagons were the most numerous. As previously noted, the effect of size differences on the shape of compressed lead spheres has also been demonstrated to affect the number of faces markedly. The cell data presented here give similar results and emphasize the importance of contact and pressure in cell shape determination.

The assumption that semi-liquid, colloidal, and plastic cells tend within limits to assume a least-surface to volume configuration is substantiated by a comparison of the surface areas of the cells with the surface areas of orthic tetrakaidecahedra of equal volume. Some of the cells observed have surface areas as economical as those of orthic tetrakaidecahedra of equal volume, and most of the cells approach the economy of surface found in this regular figure.

A study of the 100 pith cells modeled indicates that the number of faces varies most commonly between eleven and fifteen, with an average of 13.36. The cells studied may be divided into two groups, the larger ones with an average of 15.41 faces, the smaller ones with an average of 12.78, and the smaller ones are considerably more abundant than the larger. If the theoretical average for cells of uniform size is 14, as previous studies would indicate, then the preponderance of smaller cells would tend to reduce the average below 14 in the present study. Among the 100 cells there is no predominant type or pattern that is clearly evident. Six cells had four quadrilateral, four pentagonal, and three hexagonal faces, and none of the other types occurred more than three times among the cells modeled. While the average clearly approaches fourteen, it is difficult on the basis of these data to resolve these cells into one ideal shape or pattern with a definite number of hexagonal, pentagonal, and quadrilateral faces, although certain of the cells can easily be interpreted as modified orthic tetrakaidecahedra. Surface tension and contact and pressure are ostensibly of major importance in cell shape determination.

Any average or typical fourteen-sided cell would tend to become obliterated by the numerous modifying influences, such as variations in size, division of certain cells in the tissue, changes in relative viscosity, or other factors, biological as well as physicochemical. Either there is no very definite pattern superimposed on the polyhedron which is fourteen-sided, or else it becomes obliterated; the result is the same—none could be found in the mature cells

modeled and studied.

#### SUMMARY

Three-dimensional models of 100 Eupatorium pith cells were made by means of a new technique previously described.

These cells had an average of 13.36 contacts, an average rather similar to that (13.97) found by Lewis for 250 undifferentiated cells. The average number of faces approaches the average for compressed lead spheres of uniform diameter (Marvin), but the averages for large and small cells tend to resemble those found by Matzke for large and small compressed lead spheres. Assemblages of polyhedra with trihedral angles only, yet averaging less than 14 faces, are possible through certain planes of division (Lewis).

The average cell, oriented in vertical columns, presents an upper and a lower facet, with 11 or 12 lateral facets. Pentagonal faces are most common

on the cells as on compressed lead shot.

There is a correlation between the size of a face and the number of its edges: large faces have more edges than small ones. The areas observed are similar to the areas of the corresponding regular polygons with sides of unit length.

The cells show an economy of surface to volume approaching, and in some cases equalling, that of an orthic tetrakaidecahedron or a rhombic dodeca-

hedron of equal volume.

## A CASE OF CORRELATIVE GROWTH INHIBITION IN PLANTS <sup>1</sup>

F. W. Went

In the extensive work on substances affecting the growth rate of Avena coleoptile cells, practically all substances tested are either inactive or increase the growth rate. In only a few instances growth inhibitions have been reported. Almost all were demonstrated by applying a small agar block containing the substance in dissolved form to one side of the cut surface of a decapitated Avena coleoptile (Avena test). If the substance increases the growth rate, the plant will bend away from the side with the agar block (negative curvature); with a growth retarding substance a positive curvature should result. Gorter (1927) dismissed all previously recorded cases of growth inhibitors by demonstrating that in all those cases the positive curvature appeared more than 2½ hours after the last decapitation of the test plant. Positive curvatures, appearing after that period, can be accounted for by regeneration of auxin at the free cut surface, not covered by agar. Later Czaja (1934) and Laibach and Meyer (1935) reported positive curvatures with certain plant extracts, Czaja attributing them to tannins. For a more complete survey of the literature see Went and Thimann (1937). Since then a real growth inhibitor has been found and extracted (Stewart et al., 1939). The following report, however, is concerned only with substances inactive in or promoting growth.

The case of lateral bud inhibition is, of course, the best known correlative growth inhibition known. In a recent paper the author (Went, 1939a) discusses this case in the light of experiments similar to those presented in this paper, so that no further mention will be made of bud inhibition. In another paper it is shown (Went, 1939b) that in the pea test for auxin a substance must possess at least two different properties to cause the peculiar growth curvatures in the split pea stems—namely, to induce the preparatory and the growth reaction. Some substances, like indole acetic acid, are highly effective in both properties; others, although able to produce the preparatory reaction, may have diminished growth properties (phenyl acetic acid) or may have no growth promoting effect at all (hemi-auxins like cyclohexane acetic acid and γ-phenyl butyric acid). As will be seen, a clear distinction between these three groups of substances is advantageous for the understanding of the following facts.

THE FACTS ABOUT THE GROWTH INHIBITION IN AVENA COLEOPTILES BY GROWTH PROMOTING SUBSTANCES.—A. Indole acetic acid.—When high concentrations of indole acetic acid (e.g., 20 mg./l.) in agar are unilaterally applied to decapitated Avena coleoptiles, negative curvatures develop within one hour, continuing for many more hours. Occasionally there will be found a coleoptile, which shows a positive curvature below the negative. A picture of such

<sup>1</sup> Received for publication April 24, 1939.

a positive curvature can be found in Went and Thimann (1937), fig. 22, the extreme right-hand plant of the lowest row. Although the general rule is that indole acetic acid causes growth acceleration, in certain rather exceptional cases (using high concentrations) it thus may produce a growth inhibition near the base of the coleoptile.

The same phenomenon may be observed with direct growth measurements. If the growth of the zones of an Avena coleoptile be measured, a distinct distribution of the growth rate will be found (see e.g., Went, 1928, 1935). Upon application of a high auxin concentration in lanolin to the tip of the coleoptile, in all cases the growth of the middle zones will be greatly increased (see fig. 2), but again in a few individual plants the growth rates of the lowest growing zones may be decreased. Thus, although in each coleoptile the gross growth effect is an acceleration, indole acetic acid may cause a local growth inhibition of the basal zones. Isolated basal sections invariably show a growth acceleration when immersed in an indole acetic acid solution.

Because the phenomenon is too uncommon when indole acetic acid is applied it will be studied in greater detail with other compounds, having a smaller or no growth effect.

B. Phenyl acetic acid.—High concentrations of phenyl acetic acid (30 mg./l. or more) in agar, when unilaterally applied to the cut surface of decapitated Avena coleoptiles, will induce distinct negative curvatures in the extreme tip of the plants only. But below this negatively curved zone a much larger positive curvature develops from one and one-half to three hours after putting the agar on (see fig. 1A). Here the apical and basal zones simultaneously bend in opposite directions. Thus in this case, where the growth acceleration is much less than with indole acetic acid, the growth inhibition of the lower zones is more pronounced.

If not only the curvatures are considered, but also the actual growth response of the zones of the coleoptile, when lanoline paste containing phenyl acetic acid is applied to the tip of the plant, the growth of the highest zones is accelerated, but more than

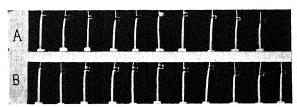

Fig. 1. Shadow pictures of Avena coleoptiles taken 165 minutes after applying agar.—Upper row (A): phenyl acetic acid 30 mg./l. applied in the agar block; S-shaped curvature (at top short negative curvature).—Lower row (B): cyclohexane acetic acid 20 mg./l. applied. Purely positive curvatures.

3 mm. below the tip the growth is greatly inhibited (see fig. 2). From another experiment can be drawn the conclusion that the higher the concentration in the lanoline, the greater the growth acceleration near the tip and the more extensive the growth inhibition in the base.

C. Cyclohexane acetic acid.—If a 20 mg./l. solution of cyclohexane acetic acid is applied unilaterally to the cut surface of an Avena coleoptile, no trace of negative curvature becomes visible, but within two hours distinct positive curvatures de-

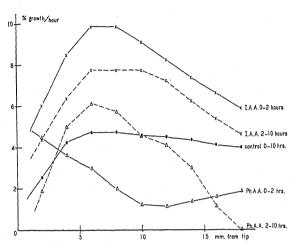

Fig. 2. Growth of the different zones of intact Avena coleoptiles (abscissa: distance of zones in mm. from tip), in percentage elongation of zone per hour (ordinate), when either pure lanoline was applied to the tip (control; black dots, growth distribution essentially identical from 0-2 and 2-10 hours after application of lanoline), or indole acetic acid paste (3 mg./g. lanoline; crosses, strong growth increase in all zones in both periods after application) or phenyl acetic acid paste (3 mg./g. lanoline; triangles). In the latter case a short apical zone of 4-10 mm showed an increase in growth rate over the controls, the lower zones a growth inhibition. The decrease in the top zone for the 2-10-hour period may have been due to slight injury. Each curve mean of 4 individual plants.

velop, which increase in size for a long time (see fig. 1B). Unlike the negative, these positive curvatures do not start in the extreme tip, but develop first at some distance from the cut surface. Substances like γ-phenyl butyric acid and indole-2-carbonic-3-propionic acid, also completely lacking any growth properties (see Koepfli, Thimann, and Went, 1938), behave in the same way.

Thus the substances mentioned under A, B, and C all are able to induce growth inhibitions in Avena coleoptiles, especially near the base; this effect may be partially (phenyl acetic acid) or almost completely (indole acetic acid) overshadowed by the growth acceleration.

D. Direct growth measurements with different substances.—A number of experiments were performed with Avena coleoptiles, on whose tip a dab of lanoline paste was stuck. Usually growth was

Table 1. Increase in length of intact Avena coleoptiles on which a dab of paste was put on tip. Mean of 6 plants each.

			th in n. in	
	Concentration		Next 13 hrs.	
Indole acetic acid	0.4 mg./g. lanoline	10.5	10.8	
Phenyl acetic acid	4 mg./g. lanoline	5.8	2.7	
$\gamma$ -Phenyl butyric acid.	4 mg./g. lanoline	2.2	1.8	
Pure lanoline		5.7	7.7	

measured twice in those coleoptiles: after 5 hours and after 18 hours. Table 1, which represents a typical experiment, shows that the indole acetic acid did increase the growth over the pure lanoline controls in both periods. In the first period the growth effect of the phenyl acetic acid kept the inhibition in check, but in the second period it gave a strong inhibition. And the  $\gamma$ -phenyl butyric acid only caused a growth inhibition, in both periods.

Here the question could be raised, whether the effect of the applied substances was on the auxin production by the tip. Therefore paste was applied to the tips of intact coleoptiles, and three hours later these tips were placed on agar. It was found that with phenyl butyric acid 2 mg./g. lanoline exactly the same amount of auxin was produced as with pure lanoline. With phenyl acetic acid 2 mg./g. about 40 per cent less auxin was collected. We must conclude then that the growth inhibition is not in the first place due to a lack of auxin. In a number of other experiments it was found that some substances, like indole carboxylic acid and the lowest concentration of y-phenyl butyric acid, did not cause any change in the rate of growth of intact or decapitated coleoptiles, as compared with the pure lanoline controls. Others, like indole acetic, indole butyric, and anthracene acetic acids, caused a strong increase in growth rate in both periods, whereas indole propionic and cis-cinnamic acids were much less effective. But again, y-phenyl butyric acid inhibited growth, in the highest concentration at least. Other experiments gave similar results.

Thus, the conclusion is well established that the substances mentioned above inhibit growth, especially of the more basal zones, of intact or decapitated *Avena* coleoptiles.

MECHANISM OF THE OBSERVED GROWTH INHIBITION.—There are at least two ways in which we can envisage the action of a growth inhibiting substance. In the first place it is possible that the substance directly interferes with the growth process. This means that we have to consider that in the growth process, requiring n factors, another has been introduced, so that n+1 factors cause a decreased growth rate. A simpler explanation is found in the assumption that one of the n factors required for growth is eliminated by the action of the substance. But not

Table 2. Three 4.2 mm. sections cut from coleoptiles (each figure mean of 10 sections). For 18 hours these are submerged (on combs) in the solutions indicated. For the next 24 hours all sections are transferred to a solution of indole acetic acid 1 mg./l. For this second period only the mean of upper, middle, and lower sections are given.

			First 18	hrs. in s	olutions		sect	xt 24 hrs ions in i c acid 1	ndole
	Concentra-		Section		Mean of all	Net increase over	Mean of all	In- crease over	In- crease over
Compound		Upper	Middle	Lower	sec- tions	con- trols	sec- tions	first period	con- trol
Water control		46.0	45.2	45.4	45.5		48.4	2.9	
Indole acetic acid	1  mg./l.	52.3	49.9	47.0	49.7	4.2	51.3	1.6	2.9
Indole acetic acid	0.1  mg./l.	49.0	48.1	$47.3^{-}$	48.1	2.6	50.0	1.9	1.6
Phenyl acetic acid	100  mg./l.	50.3	48.5	47.5	48.8	3.3	51.5	2.7	3.1
Phenyl acetic acid	10  mg./l.	49.2	48.4	47.0	48.2	2.7	50.4	2.2	2.0
Phenyl acetic acid	1  mg./l.	45.5	45.4	45.6	45.5	0	47.4	1.9	1.0

until the different growth factors are known can the latter explanation be attempted. Thus only after the rôle of auxin in growth became known, could most cases of traumatotropism be transferred from the former to the latter explanation.

And in the underlying case, where just the effect of auxin-like substances is to be elucidated, auxin cannot be the growth factor which is eliminated. This is clearly indicated by the experiment on auxin production, described above. Besides, the results of growth measurements were essentially the same when decapitated—that is, auxin-deficient—coleoptiles were used as with intact coleoptiles (in the cases of sections A, B, and D this has been studied in detail). Finally, in most of the following experiments indole acetic acid was applied in excess, so that there was no limitation by auxin-like substances.

Another growth factor, about which something is known, is the "food factor." This factor comes from the base of the coleoptile, and some growth phenomena could be explained by the assumption that auxin affects its upward transport (Went, 1935). To eliminate this supposed effect, coleoptiles were cut into short sections, which were then submerged in the solutions to be tested. In these sections a certain amount of food factor was "trapped," and applied auxin could not affect its supply any more, since the region of supply (the seed) was absent.

In one experiment three successive sections of 4.2 mm. were cut from a series of coleoptiles, which were then treated with tap water, indole acetic acid, or phenyl acetic acid (see table 2). For details concerning the technique of these determinations see Schneider (1938). From the table it will be clear that a section from any portion of the coleoptile responded to phenyl acetic acid with growth in exactly the same way as they responded to auxin, the only difference being that the concentration of the former had to be about 100 times higher. Since all acids were always made up with the equivalent amount of NaOH, and then diluted with distilled

water, the effects are not due to different pH. In these sections, especially the lower, no trace of growth inhibition with phenyl acetic acid was found. If afterwards placed in a solution of indole acetic acid, all sections grew still more, those previously in phenyl acetic acid even more than those in indole acetic acid. This proves that the sections were in no way injured by the phenyl acetic acid, so that on coleoptile sections at least it acts as an ordinary growth promoting substance, without any indication of growth inhibiting properties.

That also substances which cause only growth inhibition in the intact coleoptile have no inherent inhibiting properties on cells as such can be seen from table 3, compiled from data Dr. J. van Over-

Table 3. Growth of 6.4 mm. sections of etiolated pea stems in percentage of initial length, 4 and 24 hours after they were placed in the solution. Data collected by Dr. J. van Overbeek.

way as in table 2, that is both were true growth promoting substances. But the cyclohexane acetic acid, which induces positive curvatures in *Avena* (section C above), did not decrease the growth rate; if anything, a slight acceleration could be observed.

So far, the results obtained here seem in contradiction with those described earlier in this paper. The difference, however, lies in the plants, which were cut into short cylinders in the one and intact in the other case. This makes it clear that the inhibition is a correlation phenomenon, connected with the distribution of growth factors inside the growing organ, and most likely the factor affected is the food factor. To collect further evidence for the latter viewpoint, the following experiments were carried out:

Avena coleoptiles were treated with a dab of lanoline paste containing the active substances, which was stuck on the extreme tip of the coleoptile. After two or three hours the 2 mm. tip with paste was cut off and the rest of the coleoptile cut into four sections, each 4.2 mm. long, after removal of the primary leaf by pulling it out from the base. The growth of these sections in an auxin solution containing 1 mg. indole acetic acid per liter was measured after one day; the results of two experiments are summarized in table 4. If it is considered that in all cases auxin was in excess, it must be concluded that differences in growth were due to differences in other growth factors, that is especially in the "food factor." Since we know from the experiments from tables 2 and 3 that the substances used did not injure the sections, we come to the following results: pretreatment with y-phenyl butyric acid increased the growth of the upper sections but decreased the growth of the sections from the lower part of the coleoptile; pretreatment with phenyl acetic acid caused exactly the same effect. These results lead to the conclusion that apical administration of both phenyl acetic acid and y-phenyl butyric acid caused a redistribution of the food factor inside the coleoptile in such a way that part of the food factor originally present in the base was moved towards the more apical zones. With indole acetic acid this effect was in most cases obscured by its effect on growth during the 2 to 3 hours of pretreatment. Under the influence of the auxin the food factor was apparently used up in growth more rapidly than it was supplied (see e.g., Went, 1935), so that the final effect was a decrease in growth rather than an increase. That this explanation is correct is indicated by an experiment in which there was an increase (except in the topmost section) in growth of the sections of plants which were pretreated with indole acetic acid for one hour only.

Since these experiments were carried out, a paper by Schneider (1938) appeared in which he clearly showed that sucrose is at least one of the components of the food-factor complex. Therefore, the preceding experiments were repeated by placing the sections in a solution containing 1 mg./l. of indole acetic acid and 1-2 per cent sucrose. If the effect of the applied substances were on the sugar in the coleoptile, then this effect would disappear when placed in an excess of sucrose. But if some other component of the food factor complex were affected, the effect would remain or even be more clearly pronounced, since the sugar would not be limiting the growth. In table 5 the data of three experiments are summarized. The differences in growth of the sections after the different treatments are more pronounced than in the experiments of table 4, which indicates that to some extent sugar was limiting especially in the most rapidly growing regions, as might have been expected from the results of Schneider (1938). But it also becomes clear that something else besides sugar has been affected by the phenyl acetic and phenyl butyric acid. This clearly demonstrates that besides sugar there are other factors present in the food-factor complex. Therefore Schneider's criticism (1938), based on experiments with sugar, of the limiting factor scheme of growth as proposed by the author (see Went and Thimann, 1937) does not necessarily hold for the auxin-food factor interrelations inside the growing region.

In all experiments (of which only three are reproduced in table 5) a clear (and in most cases statistically highly significant) increase in the growth of the upper 3 or 4 mm. appeared, and in eight out of ten cases a simultaneous decrease in the growth of the basal section was found.

The same experiments were performed with peas, to find out whether the redistribution effect of growth rate is a more general phenomenon. Since the situation is complicated in peas by the growth

Table 5. Growth in percentage after 24 hours of 3.1 or 4.2 mm. Avena coleoptile sections, placed in 1-2 per cent sucrose + 1 mg./l. indole acetic acid. Two hours previous to cutting these sections, lanoline paste containing different substances was placed on the extreme tip of the coleoptile.

inhibition in the apical zones accompanying the swellings which appear after application of higher auxin concentrations, no detailed discussion will follow:

In the pea stems also the growth of the basal zones is inhibited by the more apical ones, since, after cutting these zones into sections, they grow more than on the intact plant. The same phenomenon was more clearly apparent when indole acetic acid paste 2.5 mg./g. was applied. On plants attached to their seeds the zone from 27–34 mm. from the tip grew 1.5 per cent in 24 hours. When the plant was cut off above the cotyledons, this growth was  $3\pm0.4$  per cent, but when this section was cut out from the plant, it grew  $6\pm0.3$  per cent. Thus also here apically applied auxin causes an inhibition in the lower zones of the intact pea stems, although by itself, on the isolated tissue it increases its growth.

Another phenomenon, mentioned in an earlier paper (Schneider and Went, 1938), now finds a ready explanation in the redistribution of food factor. When two hours before decapitation a small dab of auxin lanoline paste is applied to the tip of an Avena coleoptile, then in the subsequent Avena test the response of these plants to unilateral auxin application will be different. In the first place the

curvature is limited to a shorter zone near the tip of the coleoptile, and secondly the radius of curvature is decreased. This experiment was repeated several times. When indole acetic acid paste was applied, the response was not as consistent as with ciscinnamic, phenyl acetic or phenyl butyric acids. Table 6 lists some of the curvatures obtained when a 0.2 mg./l. indole acetic acid solution was applied in agar blocks to one side of coleoptiles, which had been treated for two hours with various auxins and hemi-auxins. From the length of curved zone and the total curvature the mean curvature per mm. coleoptile has been calculated. It will be seen that not only the curved zone was shorter in all treated plants, but also that the curvatures were larger, which makes for a much sharper curved zone.

Discussion.—The experiments just described give a satisfactory explanation for the facts reported in the first part of this paper. In general it can be stated that applied auxins or hemi-auxins change the sensitivity of growing cells to auxin when measured as growth in length. This effect is an increase in sensitivity near the applied auxin and a decrease further away. This might be described in terms of rejuvenation and aging, as was done before (Went, 1935), but such terms do not give an explanation.

Table 6. Length of curved zone, total curvature, and curvature per mm. curved zone in Avena coleoptiles, if immediately after decapitation agar blocks soaked in 0.2 mg./l. indole acetic acid are unilaterally applied to the cut surface. Treatment of coleoptiles in the two hours previous to decapitation indicated in first column. Curvatures measured after 90 minutes.

	Afterwards 0.2 mg. indole acetic acid/l. produces					
Substance previously applied in lanoline to tip	Length of curved zone	Curvature	Curvature per mm. curved zone			
Pure lanoline	8.0 mm.	12.9°	1.6°/mm.			
Indole acetic acid 1 mg./g	7.9 mm.	14.3°	$1.8^{\circ}/\mathrm{mm}$ .			
Indole acetic acid 0.2 mg./g	7.4 mm.	13.4°	$1.8^{\circ}/\mathrm{mm}$ .			
Cis-cinnamic acid 10 mg./g	$6.7 \mathrm{\ mm}$ .	17.6°	2.6°/mm.			
Phenyl acetic acid 2 mg./g	7.0  mm.	15.3°	$2.2^{\circ}/\mathrm{mm}$ .			
Phenyl butyric acid 2 mg./g	$6.2 \mathrm{mm}.$	14.4°	$2.3^{\circ}/\mathrm{mm}$ .			

To understand the effect of auxin on growth it has been necessary to assume the interaction between auxin and the food-factor complex (Went, 1928, 1935). To this food-factor complex belong those factors or substances with which the auxin has to cooperate, or react, to cause cell elongation. One of the food factors was identified as sugar by Schneider (1938). From the work of Mitchell and Martin (1937) and many others it appears that the application of indole acetic acid may affect the rate of carbohydrate transfer. However, this transfer has not been shown to occur previous to the morphologic responses, so that they may be ascribed to the result rather than the cause of the increased growth or root formation. In the experiments which are described here the food factor affected is not sugar, since the application of sucrose did not change the results.

Now the main fact established in this paper is that under the described conditions the reactivity of the cells near the applied auxin tends to increase, whereas further away we find a simultaneous decrease, which is of the same order of magnitude. Since we ascribe the sensitivity of the cell to its food factor content, the conclusion seems logical that under the influence of apically applied auxin this food factor is redistributed, so that it moves toward the auxin supply. This leaves a (temporary) deficit in the lower zones, which is offset as soon as the downward moving auxin has reached the source of the food factor (the seed, see Went, 1935).

Thus we see that all facts line up nicely in a general scheme when we recognize that the effect of apically applied auxin on cell elongation is two-fold. In the first place it causes or at least increases the upward transport of certain substances, necessary for cell elongation, such as the "food factor" in Avena. This effect is produced even by hemiauxins, which are substances unable by themselves to cause growth, such as cyclohexane acetic acid and  $\gamma$ -phenyl butyric acid. And in the second place they can specifically induce cell elongation in the presence of the other cell elongation substances. A very clear distinction between these two properties of the same substance is possible in the case of phenyl acetic acid. Since its growth effect is exerted in high

concentrations only, whereas the translocation effect apparently occurs in lower concentrations as well, a regional separation between the two processes is possible—a fact which is difficult to establish for the most active auxins. In the first two hours after apical application of phenyl acetic acid it causes the food factor present in the lower zones to move upward and collect in the upper zones of the coleoptile. Since during that period its effect apparently does not reach farther downward, inducing an increased supply from the seed, there is, at least temporarily, a food-factor deficiency in the lower zones, demonstrating itself in a growth inhibition. The increased food-factor supply near the tip, together with the growth promoting effect of the high phenyl acetic acid concentration, will cause a growth acceleration of the highest zones.

In these cases it has been clearly demonstrated how, through two completely different physiological activities, one substance may be promoting growth in one part of the plant and inhibiting it in another. There is not the slightest indication that concentration differences are instrumental in these qualitatively different growth responses, since in isolated pieces of tissue the effect on the different zones was always the same, independent of the concentrations. It has been sufficiently proven that in the underlying case the inhibition is *indirect* and is a correlation phenomenon. It also is clear that if a substance lacks the growth property, it still may induce a growth inhibition, since the inhibition is not exerted through extra growth somewhere else. The use of chemically different pure substances has been of great help in solving this problem, since in addition to the physiological differentiation in time and place of the activities of auxin, even a complete separation of the translocation and growth activities with different substances was possible.

In conclusion one might ask what importance these experiments have in elucidating normal growth. The substances used in this investigation are partly not naturally occurring in plants, and besides, the concentrations employed are far beyond what normally would occur. The main point is that by affecting the movement of other growth factors, inhibitions may be caused by growth promoting sub-

stances. This same type of growth inhibition was shown to occur in lateral bud inhibition (Went, 1939a), so that these two cases mutually confirm each other. It is believed that the naturally occurring auxins affect growth in the same way as described above for the high concentration of phenyl acetic acid, for example. This accounts then for the food factor moving toward the growing point of a stem and for the decreased auxin sensitivity of the lower zones of the growing stem, where aging occurs. A similar case of auxin affecting the translocation and accumulation of other growth factors was described in the case of root formation by Cooper (1938) and Went (1938). A further discussion of this problem will appear elsewhere.

APPENDIX.—In this connection another growth inhibition should be discussed. Recently Snow (1937) described two new growth promoting substances. In another connection (Koepfli, Thimann, and Went, 1938) it has been shown recently that for at least one of these substances, dibenzoyl peroxide, this claim is erroneous. If this substance is mixed with lanoline and smeared along one of the sides of an Avena coleoptile, the coleoptile will continue to grow straight for about half a day, but then shows a tendency toward a positive curvature, as far as the lanoline extends along the coleoptile. This also seems a case of growth inhibition, and the substance was investigated in a section-growth test. Table 7 shows the results. Ten coleoptile sections of

Table 7. Growth in mm. of 4.2 mm. Avena coleoptile sections. First treatment 17 hours, second treatment next 24 hours.

First treatment		Second treatment, all in indole acetic acid 1 mg./l.
Indole acetic acid 1 mg./l	1.48	0.06
Benzoyl peroxide satd	0.52	0.11
Water	0.51	1.42

4.20 mm. length were placed in each of the following solutions: water, a saturated dibenzoyl peroxide solution, and indole acetic acid 1 mg./l. In the first 17 hours there was a good growth effect in the auxin solution, but growth in water and in dibenzoyl peroxide was the same. This proves that this substance is no growth promoting substance at all. For the next 24 hours all sections were transferred to an indole acetic acid solution 1 mg./l. Those previously in auxin hardly grew at all; all food factor had

been used up in growth in the previous period. Those coming from water grew a fair amount, proving that unused food factor was still present in the sections. But the sections coming from the dibenzovl peroxide did not grow any more. Thus under the influence of this substance the food factor seems to have disappeared, probably by destruction. Since the growth in the first period was not affected, it hardly can have affected the auxin. Besides, if it did do so, a more immediate response in the bending test could be expected. There were also no indications that the lack of growth was due to toxicity, the cells remaining turgid. Thus it seems that in dibenzoyl peroxide we possess a substance which is directly inhibiting growth through its effect on the food factor.

#### SUMMARY

Occasionally after application of high concentrations of indole acetic acid, but regularly with phenyl acetic, cyclohexane acetic, or  $\gamma$ -phenyl butyric acids, a growth inhibition of the lower zones of an Avena coleoptile occurs. This inhibition is demonstrated by direct growth measurements, both of whole coleoptiles and of zones of intact plants, but more easily by unilateral application of these substances to the cut surface of decapitated coleoptiles (Avena test), when they show positive curvatures within  $2\frac{1}{2}$  hours after application.

This growth inhibition is an indirect effect of these substances, observable only in intact or decapitated plants, but absent in short coleoptile or pea stem sections. Experiments have indicated that the inhibition is due to removal of other growth factors (in the Avena coleoptile the food factor) from the zone of inhibition, which are then accumulated near the place of application of the active substances (the tip). Thus it is clearly proven that the effects of substances like phenyl acetic acid (and by inference also for indole acetic acid) on growth are due to a dual action; in the first place they redistribute other growth factors, and in the second place they react with those other factors to give cell elongation. Some substances (cyclohexane acetic acid, γ-phenyl butyric acid) possess only the property of redistributing the other growth factors without directly affecting cell elongation.

In one case, dibenzoyl peroxide, experiments indicated that the growth inhibition caused by this substance is probably due to its effect on the food factor.

## A NEW FUNGUS WITH ANTERIORLY UNICILIATE ZOOSPORES: HYPHOCHYTRIUM CATENOIDES <sup>1</sup>

### J. S. Karling

In a series of attempts to inoculate bits of young Zea mays leaves with Physoderma zeae-maydis in Petri dishes for the purpose of securing the ephemeral zoosporangia of this chytrid, another unusual fungus appeared in the trichomes along the leaf margins. The origin of this fungus is uncertain, but it may have been introduced with the inoculum of Physoderma resting spores. In these experiments young unfolded and delicate leaves of corn were washed in several changes of distilled water, and strips of the leaf margins with trichomes were then placed in Petri dishes partly filled with sterile charcoal water. To these was added a dense suspension of *Physoderma* resting spores. Approximately ten days later, after the leaf margins had died and were being attacked by protozoa and bacteria, the new fungus made its appearance in the trichomes and soon spread to adjacent epidermis and parenchyma cells. So far, zoospore infection of normal healthy trichomes in which the protoplasm was still streaming has not been observed, but young thalli have been found in palisade cells of which the plastids were still green and appeared to be normal. Attempts to infect living and dead trichomes of cucurbits, tomatoes, and potatoes, root hairs of wheat, barley, and rve, as well as cooked filaments of Cladophora and Oedogonium have failed. The fungus, however, will infect and grow well in cooked internodes of Chara and Nitella. It is apparently parasitic to some degree but grows best in dead cells and on synthetic nutrient media.

Bits of heavily infected corn leaves were transferred to 1 per cent potato-dextrose and corn meal agar, and within four days the fungus had spread onto and made slight growth in these media. Transfers were made at once, but, since the fungus grows very slowly, it has been difficult to free it from bacteria. The addition of 4.68 per cent potassium thiocyanate, according to Bojanovsky's (1938) method, to corn meal and dextrose agars has retarded the growth of bacteria to some extent, but so far it has not proven of much value in securing pure cultures.

1 Received for publication April 29, 1939.

Cultures on agar when flooded with a thin film of sterile charcoal water form zoospores in a few hours which disperse very rapidly. These come to rest and germinate as the water evaporates, and it is thus possible to pick up isolated spores and establish pure monospore cultures. So far, this fungus seems to grow best on 1 per cent corn meal and potatodextrose agars, which are sufficiently soft to permit penetration and spread of the thallus.

In trichomes of corn this fungus is often strikingly like Catenaria except for the lack of rhizoids, while in parenchyma cells and on agar it may frequently resemble Myzocytium. It differs fundamentally from species of these genera, however, by the presence of a single anterior cilium on the swarmspores. This character, together with the similarity in structure of the thallus and the lack of rhizoids, seems to indicate a close relationship with Hyphochytrium as this genus is now known. For the time being I am accordingly including my fungus in this genus and designating the species as catenoides with the purpose of emphasizing the general appearance of its thallus.

HYPHOCHYTRIUM catenoides Nov. sp.—Thallus predominantly polycentric and intramatrical; usually hypha-like, and consisting of a linear series, up to 500  $\mu$  in extent, of intercalary and terminal swellings and sporangia connected by tubular hyphae or isthmuses 1 to 38  $\mu$  in length and 2.2 to 4  $\mu$  in diameter; occasionally monocentric, oval, elongate, spherical and Olpidium-like. Zoosporangia terminal or intercalary, delimited by cross septa, hyaline, smooth, spherical, 10–35  $\mu$ , oval, 10 $\times$ 12  $\mu$ –18 $\times$ 22  $\mu$ , broadly spindle-shaped  $6\times10~\mu-9\times18~\mu$ , elongate and sometimes slightly irregular with 1-4 single or branched, straight, curved, coiled, or irregular exit tubes,  $5-250 \mu$  in length and  $3-6 \mu$  in diameter. Contents of sporangium usually emerging as a naked spherical mass on the outside and undergoing cleavage into swarmspores; occasionally undergoing complete or partial cleavage in the sporangium whereafter the segments glide out in succession. Zoospores anteriorly unicilate, slightly flattened, oval, and elongate,  $1.5\times3.5~\mu-2\times3~\mu$ , with several small, slightly refractive granules. Sexuality and resting spores unknown.

Weakly parasitic and saprophytic in Zea mays, Nitella flexilis, and Chara coronata in New York

HYPHOCHYTRIUM catenoides Nov. sp.—Thallo praecipue polycentrico atque intramatricali; semper fere hyphae simili, constato ordine, usque 500  $\mu$ , intercalarium atque terminalium tumorum et sporangiorum tubularibus hyphis vel isthmis 1-138 μ long.  $\times$  2.2-4  $\mu$  dia. conjunctorum; aliquando monocentrico, ovato, longius facto, globoso, Olpidio simili. Zoosporangiis terminalibus vel intercalaribus, parietibus disjunctis, hyalinis, levibus, globosis  $10-35 \mu$ , ovatis  $10\times12 \mu-18\times22 \mu$ , fusiformibus  $6\times10~\mu-9\times18~\mu$ , longius factis atque aliquando leviter irregularibus, uno usque quattuor, solis vel ramosis, directis, flexis, tortuosis, vel irregularibus tubulis dimissionis, 5–250  $\mu$  long. atque 3–6  $\mu$  dia. praeditis. Quibus continet sporangium cumulo nudo globoso semper fere extra emergentibus, et zoosporis ruptis; aliquando absolute vel aliquatenus sporangio ruptis, segmentis ordine inde elapsis. Zoosporiis cilio anteriore praeditis, planis, ovatis, et longius factis,  $1.5 \times 3.5 \mu - 2 \times 3 \mu$ , multis parvis refractis globulis praeditis. Sexualitate atque sporis perdurantibus incompertis.

STRUCTURE AND DEVELOPMENT OF THE THALLUS. -The thallus of H. catenoides is usually polycentric, hyaline and greyish-granular in color, and consists of linear series of spherical, oval, broadly spindle-shaped or fusiform swellings and sporangia connected by short isthmuses or tubular hyphae of variable lengths. Figure 15 shows an unusually extensive, branched thallus from a large trichome of corn with ten swellings and sporangia in various stages of maturity. In such host cells the appearance of the thallus is usually very different from that in agar cultures. It is usually less branched and crowded and more often consists of a single row of rather widely separated sporangia connected by long, tubular, septate, hyaline, and empty hyphae of fairly uniform diameter, as is shown in figure 16. This particular thallus measured 500  $\mu$  in over-all length. The length of the connecting hyphae may vary from 10 to 138  $\mu$ , and in some instances they are reduced to mere isthmuses,  $1-5 \mu$  in length. They are usually fairly uniform in diameter, 2.2  $\mu$ - $4 \mu$ , but in some instances they may be rather irregular and much thicker. This is particularly evident in the extensions emanating from sporangia B and D of figure 15. Such structures are very common in agar cultures and may later mature into elongated irregular sporangia. The septa are fairly distinct and extend completely across the hyphae. Numerous tests with chloro-iodide of zinc have been made on the entire thallus, but no cellulose reaction has been observed.

The thalli may occasionally be very much shortened and crowded in the small trichomes and have the beaded appearance shown in figure 17, which is very similar to that of *Myzocytium* species growing in filamentous algae. In such thalli the connecting isthmuses or hyphae may be lacking altogether, so that the sporangia are separated only by transverse septa at the constrictions. Reduced monocentric thalli of the type shown in figure 18 may also occur, but they appear to be comparatively rare in cells or trichomes of corn. On agar, however, they may be very abundant and appear to be nothing more than quiescent spores which have enlarged into spherical or oval sporangia. In these cases the empty hyphal arms, such as those shown in figures 15A and 18, may be lacking, and such thalli are strikingly similar to those of Olpidium. In trichomes of small diameter these spherical monocentric thalli may expand to the limits of the side walls, and any further growth must accordingly occur in a linear direction. As a result the thalli become elongate and cylindrical with rounded ends, and completely fill local portions of the small trichomes. It is to be noted in this connection that monocentric thalli similar to those reported above have already been described by Valkanov (1929) in H. Hydrodictii. In soft agar the thallus may grow more or less radially so that the colony may become globular or almost spherical in outline. A more detailed account of its growth and appearance in such media will be given later in connection with a cytological study of nuclear and cell division, development, and organiza-

The development of the thallus can be followed very easily in the hyaline, almost transparent trichomes and on thin films of agar. The zoospore germinates readily in water and on the surface of the host and forms a germ tube which pierces the host wall and then swells up to form the primary enlargement or sporangium. In old thick-walled trichomes the hole or canal in the wall made by the penetrating tube is usually quite evident, as is shown in figures 11, 12, and 13. So far, no persistent zoospore cases have been observed as in H. Hydrodictii. Figure 5 shows an early germination stage in water outside the host cell. Sometimes two and three germ tubes may develop, as is shown in figure 6. These tubes are usually fairly thick, hypha-like, and blunt at the apex. Figure 7 shows the germination of one of the large multiciliate zoospores which often occur in this species. In figure 8 most of the protoplasm has passed down into the germ tube, leaving the zoospore case partly empty, while the primary enlargement is forming as a swelling of the tube. This does not always occur, however, since in agar cultures particularly, as has been noted above, the zoospore itself may frequently grow directly into the primary enlargement or sporangium (fig. 9). Sometimes the primary enlargement may become elongated and irregular like the one from a trichome of corn shown in figure 10.

In figures 11 to 14 are shown successive developmental stages of a thallus within a trichome of Zea mays. The earliest stage (fig. 11) appeared as a globule lying against the inner layer of the cell wall, but there was no evidence of a germ tube or empty zoospore case on the outside, although the penetra-

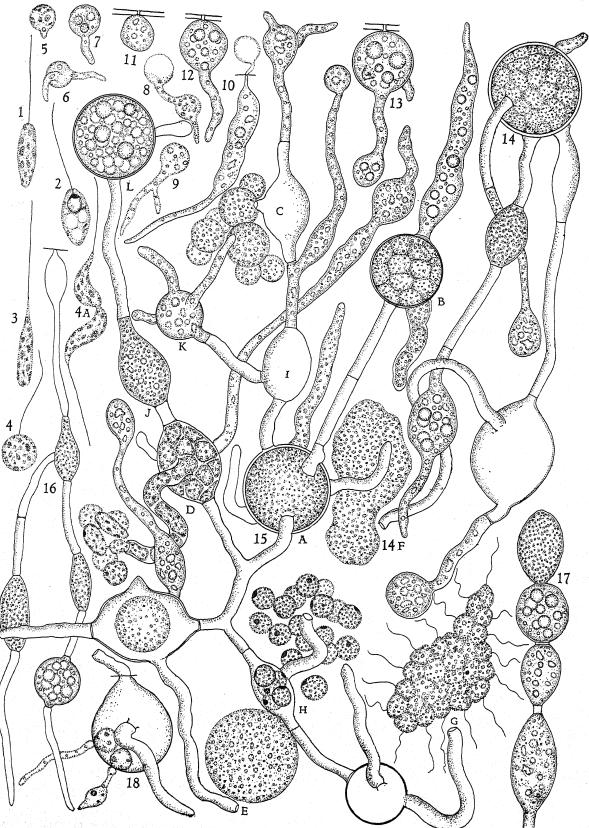

Fig. 1-18.

tion pore was quite visible in the wall. Even at this early stage numerous oval and irregular granules occur in the cytoplasm, but they do not appear as glistening and refringent as those present in the majority of the chytrids. The protoplasm as a whole has a different appearance from that of most rhizidiaceous chytrids and looks more like that of Pythium. Figure 12 shows the thallus four hours later. The primary enlargement has doubled in size, while the more refractive material of the cytoplasm has greatly increased in amount. On the under side a thick tubular hypha has grown out. Five hours later the thallus had the appearance shown in figure 13. The initial hypha has begun to enlarge at its tip and thus has formed the rudiments of a second enlargement, while two additional hyphae are forming on the primary enlargement. The number of hyphae which grow out from a single enlargement may vary from one to ten, but not all of them reach great length or continue to grow. Oftentimes their protoplasm is retracted into the enlargement again, and they are then delimited by cross walls, leaving them hyaline and empty. Two such short empty hyphae are shown at the right and left of the sporangium in figure 15A and one each in figures 15L and 18.

Within thirty-two hours the thallus had developed to the extent shown in figure 14. The primary enlargement has become a sporangium with a short exit tube, and its content has undergone cleavage into zoospore initials. One of the hyphae has formed a large egg-shaped sporangium with a curved exittube, which has emitted its contents in preparation for zoosporogenesis (fig. 14F). The initial hypha has formed two enlargements, while a terminal one is forming on the third hypha. This thallus had a limited growth, and eventually all the enlargements were transformed into zoosporangia. It none the less illustrates clearly the characteristic type of growth of this fungus. As the intercalary enlargements and incipient zoosporangia develop, the protoplasm usually accumulates in them, leaving the tubular hyphae empty and delimited by cross walls. From the enlargements secondary, tertiary, etc., hyphae grow out, and the same type of structure and organization is continually duplicated. The rudiments of the enlargements and zoosporangia usually begin as swellings at the tip of the hyphae. Their origin is thus terminal, but as new hyphae grow out from them, they become intercalary in position. As far as my observations go at present, most of the enlargements are usually transformed into zoosporangia, but occasionally the protoplasm of the primary and secondary enlargements may pass on completely into the hyphae, leaving them empty, as is shown in figures 14, 15I, and 16. In such cases they are strikingly similar to the intercalary "Sammelzellen" of the Cladochytriaceae. The hyphae may also oftentimes branch at or near the apex, which leads to the development of a thallus like that shown in figure 15.

True proliferation of the sporangia occurs very rarely, if at all, according to present observations. Quite frequently, however, one or more zoospores which have failed to emerge may enlarge and develop into monocentric olpidiaceous thalli within the old sporangia, and such appearances may easily be mistaken for true proliferation. As I have pointed out elsewhere (Karling, 1937) in relation to other chytrids, however, this does not constitute true proliferation but is merely germination in situ. Germination in situ in the manner shown in figure 18 is not

uncommon in this species.

Sporogenesis.—The sporangia are terminal or intercalary and vary from spherical, 10-35  $\mu$ , oval,  $10\times12~\mu$ -18 $\times22~\mu$ , broadly fusiform,  $6\times10~\mu$ - $9 \times 18 \,\mu$ , to elongate and slightly irregular in shape. During maturation they develop one to four, single or branched, straight, curved, coiled, or irregular exit tubes which may vary from 5 to 250  $\mu$  in length and 3 to 6  $\mu$  in diameter. The very long exit tubes are usually developed when a thallus is transferred from agar to a hanging drop of water or nutrient solution. Under such conditions they may sometimes elongate to such an extent that most of the protoplasm in the sporangia is expended by their growth. As a result, the protoplasm may become so vacuolate and spent that no zoospores are formed. While exit-tube development is going on, the coarsely granular and somewhat refractive protoplasm begins to change in appearance and becomes more finely granular and glistening-grey in color. This change seems to take place as the result of an increase in dispersion of the more refractive material. It may remain in this condition for several hours, but shortly before the protoplasm escapes from the sporangium the small granules usually begin to undergo Brownian movement. This movement extends up into the exit tubes and seems to increase in intensity with time. In a few minutes the tip of the tube deliquesces, and the protoplasm streams out rapidly to form a naked spherical mass, as is shown in figure 15E. The emergence of the protoplasm occupies from 15 to 32 seconds, depending primarily on the size of the sporangium. Sometimes a portion of the protoplast may be left behind in the sporangium where it usually rounds up into a spherical mass.

The protoplasmic mass which emerges is entirely naked, and so far I have failed to observe the presence of a vesicular membrane as in Lagena, Pythium, etc. The Brownian movement of the granules usually continues for a short time, but gradually slows down and ceases within 65 to 98 seconds. Before this ceases, however, the mass begins to change, and within 30 to 50 seconds it may have become somewhat irregular in shape (fig. 14F). Within 120 to 150 seconds the first evidence of cleavage furrows appears, and after the lapse of 156 to 180 seconds since the mass first emerges, the cleavage segments begin to show individual movement and to glide upon each other. The cilia on the segments appear within 200 to 250 seconds and stand out more or less radially from the mass of segments (fig. 15G). They begin to wave back and forth at once, and as a result the whole mass begins to vibrate and oscillate. The zoospore initials continue to glide upon each other slowly and tug to get apart, and within 420 to 475 seconds they separate and swim away. The emergence of the protoplasm and the whole process of zoospore formation may take less than eight minutes. The zoospores may often fail to swim away, and after a few minutes of wiggling about they come to rest and round up in a loose mass near the exit tube, as is shown in figure 15H. Such masses closely resemble those of Achlya, but although I have kept them under observation for several days, I have so far failed to find any evidence of diplanetism.

Oftentimes cleavage may be unequal and incomplete, so that irregular bi-, tri-, quadriciliate, etc., masses are formed. Uniciliate segments may be partially delimited in such masses and then ensues an active tug of war on the part of the units to free themselves. One may thus frequently find 2, 3, 4, and 5 segments straining in opposite directions to get apart. They often succeed in doing so and swim away, but, failing to do so, they frequently unite again into a large spherical mass after a long period of activity. In cases where two segments are involved they may often give the misleading appear-

ance of fusing gametes (fig. 4A). The method of sporogenesis described above appears at present to be the most common and normal type, but several variations of the process have been observed. If the exit tube fails to open, the content of the sporangia may undergo cleavage into segments, as is shown in figure 15B. Under such conditions the segments are usually so tightly packed together that little or no movement is visible. The segments soon round up and may remain in this quiescent condition for several days before disintegrating. Oftentimes the exit tube does not open until after cleavage within has been completed, and then the individual zoospores glide out one by one, as in figure 15D. As the pressure is thus released, those still within may swarm very rapidly. Sometimes cleavage may be only partially completed when the exit tubes open, and in such cases individual zoospore initials and large uncleaved masses of protoplasm may emerge in succession. Such segments and masses usually round up near the mouth of the exit tube without becoming actively motile or undergoing complete cleavage. They may persist in this state for several days and then germinate (fig. 7) or finally disintegrate. The large masses are doubtless multinucleate, but I have not stained any of them to determine whether or not the nuclei fuse before germination occurs.

It is obvious from the above account that the process of sporogenesis varies markedly in H. catenoides, and in this respect it is more similar perhaps to species of Lagenidium and Myzocytium than to Hyphochytrium as it is now known. In H. infestans and H. Hydrodictii, Zopf and Valkanov describe the zoospores as being completely formed in the sporangia, emerging singly in succession, and swimming directly away. In H. catenoides, on the other hand, as has been noted above, such a method of sporogenesis and subsequent behavior of the zoo-

spores appears to be exceptional as far as my observations go at the present time.

ZOOSPORES.—The zoospores are oval and somewhat flattened in shape, and as a consequence, they appear quite different in optical and side views. Figures 1 to 4 show zoospores in both views and in various stages of motility. In side view they have the appearance shown in figure 1 with a blunt or tapering anterior and a more slender posterior end, and in this view they measure  $1.5 \times 3.5 \,\mu$ . Oftentimes they are even more drawn out so as to appear as rods about three times as long as broad. Figure 2 shows a fixed and stained swarmspore in optical view,  $2\times3$   $\mu$ , with a well-defined nucleus and several conspicuous vacuoles. In the protoplasm of living zoospores numerous small granules are present which imparts a greyish, granular, and somewhat glistening appearance to the swarmspores as they swim about. These granules appear to become fewer in number toward the end of the motile period, as if some of the smaller granules had coalesced to form 4 to 8 larger ones.

The most striking structure of the zoospores, however, is a single, 7 to 10  $\mu$  long, conspicuous, anteriorly attached cilium which is directed forward as the spores swim about. During the active swimming stage the spores move so rapidly that the cilium is usually invisible in transmitted light, but in a ½ per cent agar or a syrupy gelatin medium the movement of the spore is retarded to such an extent that the position and action of the cilium may be readily observed. Under such conditions, it may extend out more or less straight in front with the end lashing back and forth. The zoospore thus moves forward in a fairly straight path, and when the cilium comes into contact with an object, it gives a vigorous lash which causes the spore to back out. It then starts off in another direction. This backward movement of the zoospore under such conditions is very characteristic, and from observing it, one might get the impression that the cilium is posterior, but when the swarmspore is swimming steadily forward, the cilium can be clearly seen out in front. Actively swimming zoospores have frequently been fixed with osmic acid and stained in toto to determine the presence or absence of a second shorter cilium. Occasional large isocont bi-, tri-, and quadriciliate spores have been found, but these appear to have arisen by unequal cleavage. More than 95 per cent of the fixed and stained zoospores so far studied have been uniciliate, and no second, shorter cilium has been observed. While moving forward, the zoospore may frequently roll over, presenting optical and side views in alternate fashion. In a less viscid and more watery medium this rolling motion may often be even more conspicuous. In water mounts the zoospores change direction so frequently and rapidly that their movement may often appear to be a darting one. It none the less appears to be quite different from that of most chytrids.

In dilute agar media and gelatine such as described above, the zoospores may often become amoeboid and undergo conspicuous contortions and

changes in shape. The anterior end may be drawn out into a tapering filament as is shown in figure 3. In other instances pseudopods may push out at various places on the periphery. The period of active motility usually varies from 20 to 80 minutes according to present observations, but in exceptional cases it has lasted as long as 3 hours. As the zoospores begin to slow down they become more globular in shape, and after coming to rest, they are usually spherical, as is shown in figure 4. At this stage the cilium may continue to vibrate for a few minutes, imparting a slight oscillating movement to the body of the spore. This movement becomes slower and slower and eventually ceases.

It may be worth while to note here that Rhizo-phlyctis Petersenii and Nowakowskiella elegans have been found in abundance in bits of corn leaves during the course of this study. The latter has been isolated in pure culture on corn meal agar and is now growing vigorously. On this medium the rhizo-mycelium becomes very extensive and comparatively coarse.

Discussion.—Whether or not H. catenoides is identical with H. infestans or H. Hydrodictii will not be certain until the latter species have been studied more intensively and the life cycles of all three are fully known. At present, however, H. catenoides shows several distinctive differences. Its zoospores are elongate, oval, and slightly flattened instead of spherical, as in the other species, and do not possess a single, highly refractive globule. In addition, the normal and more usual method of sporogenesis is quite different from that reported for H. infestans and H. Hydrodictii. Furthermore, the presence of elongated exit tubes in H. catenoides is another striking difference, but whether or not this character is of fundamental significance is not vet certain. None the less, I believe these differences are sufficient to warrant the establishment of a new species.

In the event H. catenoides proves to be a valid species of Hyphochytrium, its discovery confirms Zopf's (1884) and Valkanov's (1929) observation on this genus and their demonstration of the existence of a group of fungi with hypha-like thalli and anteriorly uniciliate zoospores. This genus was established by Zopf for a parasite on the ascocarps of Helotium, which is characterized primarily by anteriorly uniciliate zoospores and a non-rhizoidal mycelioid thallus with terminal and intercalary swellings and sporangia. Since that time Hyphochytrium, as well as all other genera, Latrostium, Reesia, etc., in which anteriorly uniciliate swarmspores are reported to occur, have been regarded with considerable doubt and skepticism. Vuillemin (1908) expressed the belief that H. infestans is nothing more than a hypha of another fungus parasitized locally by a monocentric olpidiaceous chytrid. Minden (1915) is inclined to agree with Vuillemin and changes the genus name to Hyphophagus in order to avoid confusion in relation to his restricted usage of the family name Hyphochytriaceae. In 1929, however, Valkanov found another species, H. Hydrodictii, parasitizing young cells of Hydrodictyon, and his observations thus placed the genus, as defined by Zopf, on a firmer foundation. Mycologists since then have, none the less, either looked upon it as a doubtful genus (Fitzpatrick, 1930) or disregarded it completely (Gwynne-Vaughan and Barnes, 1937). My observations lead me to believe that Zopf's genus is valid and that distinct provision must be made in our classification for a group of fungi with swarmspores of this type.

Like most algologists and mycologists, I am strongly of the belief that the number, position, and relative lengths of the cilia are fundamentally significant in classification and phylogeny, and also indicative of relationship, and for this reason I do not believe Hyphochytrium can be included in a family other species of which are characterized by posteriorly uniciliate zoospores. I am accordingly proposing the establishment of a separate family for Hyphochytrium and other similar fungi which may possibly be found in the future. Since Fischer's (1892) family Hyphochytriaceae already bears the same prefix as in Hyphochytrium, I propose, in the interests of clarity, to adopt and restrict it rather than suggest a new family name.

The name Hyphochytriaceae has been variously used in the literature, and very few mycologists are agreed as to what genera should be included in it. Fischer used this name synonymously with the Cladochytriaceae, but Schroeter (1897) distinguished it from the latter and limited it to Catenaria, Hyphochytrium, Polyrhina, and Tetrachytrium. Lotsy (1907) included only Hyphochytrium in this family, but he changed the spelling to Hyphochytridiaceae. Minden (1915), on the other hand, excluded Hyphochytrium (Hyphophagus) entirely and limited the family to Macrochytrium and the two doubtful genera, Tetrachytrium and Zygochytrium. Gäumann (1926), Gäumann and Dodge (1928), and Gwynne-Vaughan and Barnes (1937) restricted it to Macrochytrium alone, while Fitzpatrick (1930) did not recognize the family as being valid. Bessey (1935) followed Minden's viewpoint with the exception that he included Hyphochytrium, and placed the family Hyphochytriaceae among the Monoblepharidales. It is thus obvious that there is but little agreement as to the limits of this family and what genera are to be included. In view of this, a further change will not violate any well-established and generally agreed upon precedence of family name, and I thus propose to restrict the Hyphochytriaceae to species having non-rhizoidal, hypha-like or mycelioid, predominantly polycentric thalli with terminal and intercalary swellings, sporangia, and resting spores, and anteriorly uniciliate swarmspores. In this sense the family now includes one genus and three species.

For species with similar thalli and posteriorly uniciliate zoospores, I suggest the family name Myceliochytriaceae. This family would accordingly include at present Coenomyces Deckenback (1903), Megachytrium Sparrow (1931, 1933), and possibly Macrochytrium Minden (1902, 1923). On the

basis of thallus structure, Tetrachytrium and Zygo-chytrium might be listed provisionally in this connection as of very doubtful relationship, but at present this would be highly questionable, because of the types of sexuality which they exhibit. For the time being and in our present state of knowledge concerning the chytrids, the Myceliochytriaceae may perhaps be regarded as the climax family of the chytridiaceous species on the basis of size, complexity, structure of the thallus, and its similarity to the mycelium of the higher fungi. The idea that this family may be a connecting link with the Blastocladiales is very suggestive and stimulating, but so far we have but little supporting evidence.

As to where the family Hyphochytriaceae, in the restricted sense used in this paper, belongs among these simpler fungi is of course uncertain at the present time. Students of the Chytridiales are inclined to regard this so-called order as a provisional and convenient dumping-ground for a heterogeneous group of relatively simple fungi, or to limit it to a comparatively small and simple species with posteriorly uniciliate zoospores and exclude those with biciliate swarmspores. The latter students would accordingly exclude the family Woroninaceae and Ectrogellaceae as close relatives possibly of the Lagenidiales<sup>2</sup> and Saprolegniales and designate the members of the Olpidiaceae, Synchytriaceae, Rhizidiaceae, and Cladochytriaceae as "true chytrids" of definite relationships. While I agree that there are at present no very good grounds for linking the latter four families with the former two, none the less I believe that our knowledge of this so-called order as it now stands is still too meager to draw any definite and final conclusions as to phylogenetic groups. With the increasing interest in these relatively simple fungi, new genera and species will doubtless be discovered which may possibly upset our current opinions completely. Furthermore, since our present system of classifying the chytrids is

<sup>2</sup> Since Miss Berdan (1938) has shown that *Ancylistes* no longer relates to this group, the ordinal name Ancylistales is not tenable. I therefore suggest raising the family Lagenidiaceae to ordinal rank for the time being until its relationship becomes better known.

based largely on vegetative characters, it is to a large degree artificial and will naturally have to be modified as the types of sexual reproduction in the group become better known. For these reasons I regard the so-called order Chytridiales at present as a heterogeneous group of comparatively simple species which may indicate several lines of relationship and am including the family Hyphochytriaceae as a member of this order.

#### SUMMARY

Hyphochytrium catenoides has been found as a weak parasite and saprophyte in trichomes and parenchyma cells of Zea mays and in cooked internodes of Chara and Nitella. It is characterized primarily by anteriorly uniciliate zoospores and a predominantly polycentric, non-rhizoidal, hypha-like thallus with terminal and intercalary swellings and zoosporangia connected by tubular isthmuses or hyphae of varying length. In sporogenesis the contents of the sporangia usually emerge through exittubes of variable length as a naked mass and undergo cleavage into zoospores on the outside without the formation of a hyaline vesicular membrane. Oftentimes, however, partial or complete cleavage may occur within the sporangia, and in such cases the zoospores may frequently swarm first within the sporangium, then emerge in succession, and swim directly away. So far, no evidence of sexuality or resting spores has been found.

The discovery of this species supports Zopf's and Valkanov's observations on the genus Hyphochytrium and their demonstration of the existence of hypha-like fungi with anteriorly uniciliate zoospores. It is accordingly proposed that the family Hyphochytriaceae be restricted to fungi of this type. Another family, Myceliochytriaceae, is suggested for similar chytridiaceous fungi with posteriorly uniciliate zoospores. This latter family would include at present Coenomyces, Megachytrium, and possibly Macrochytrium.

### THE CYTONUCLEAR RATIO IN DEVELOPING PLANT CELLS 1

Vivian V. Trombetta

MUCH WORK has been done on the problem of the nucleocytoplasmic ratio in plant cells, but although the literature is very extensive, the results still remain confusing and often contradictory. The purpose of the present study was twofold—to determine the quantitative relationship of nucleus to cell in meristematic plant cells and to show how this relationship is altered as these meristematic cells de-

velop to their mature condition. The problem of the ratio of nuclear volume to cell volume has been studied extensively in both plants and animals, and in many cases definite relationships have been found to exist. Sachs (1892, 1893) and Strasburger (1893) noted the relative minuteness of meristematic cells and concluded that the working-sphere of the nucleus must be a very restricted one. Strasburger obtained a ratio of 2:3 for the average diameters of nuclei to cells in terminal meristems, measurements which led him to believe that a very close correlation exists between nuclear and cell size. Conklin (1902) showed that the relation of nucleus to cell is maintained in decreasing cell size in the cleavage of the ovum in annelids and gasteropods, where marked inequalities of division are frequently found; although the daughter nuclei are equal in size after division, they grow to a size which is roughly proportional to that which the cell attains. Koehler (1912) found a very marked increase in the total volume of the nuclei in the cleavage of Strongylocentrotus, up to about the ninth cleavage, whereas the volume of the cytoplasm remained unchanged. Guillermond (1909) found that the nuclear diameter always remains approximately proportional to that of the cell in Endomyces fibuliger and Saccharomyces capsularis. Henneberg (1915) obtained similar results on Saccharomyces. Teissier (1927) demonstrated in oogenesis in Hydractinia echinata that the dimensions of the nucleus increase less rapidly than the dimensions of the cell, but that the relative rates of change of nucleus and cell are constant.

<sup>1</sup> Received for publication May 2, 1939.

The author wishes to express her sincere appreciation to Professor Edmund W. Sinnott, under whose direction this work was carried out, for advice and criticism throughout the course of this study. Part of the work was done while the writer was recipient of the Grace Potter Rice and Herbert M. Richards Fellowships of Barnard College.

The nucleo-cytoplasmic ratio has frequently been studied in cases of polyploidy. In 1902 Gerassimow obtained races of Spirogyra with double the original nuclear volume and found that the size of a cell is a function of the mass of its nuclear substance. Winkler (1916) also found the size of cells of giant tetraploid individuals of tomatoes and nightshades to be dependent upon nuclear size. Similar results were obtained from a study of Oenothera gigas by Gates (1909). Lindstrom and Humphrev (1933) found cell size and nuclear size to be related to chromosome number in tetraploid tomatoes. Boveri (1905) showed that the size of both nucleus and cell in echinoderm larvae is dependent upon the chromosome number and not merely upon the amount of chromatin contained in the nucleus; he concluded that it is the surface of the nucleus, rather than its volume, which is proportional to the number of chromosomes and that the size of the cell is proportional to nuclear surface and chromosome number. Erdmann (1908) concluded from investigations on sea urchins that chromosomal mass, rather than chromosomal number is related to cell size.

Several studies have been made on the relation of chromosome number, nuclear size, and cell size in polyploid mosses which have been produced by artificial apospory. The Marchals (1909) found the volumes of nuclei and cells of Amblystegium, Physcomitrium, and Funaria to be directly proportional to the number of chromosomes. Cells and nuclei of the tetraploids are approximately twice those of the diploid; those of the diploid, twice those of the haploid. Wettstein (1924) found an increase in cell size in polyploid mosses, but the increase was not directly proportional to chromosome number. Very little is said about nuclear size in Wettstein's work. If it is proportional to chromosome number, as Boveri and most other workers have found to be the case in other forms, then a definite relationship exists between cell size and nuclear size in mosses. The dimensions of the nucleus evidently increase less rapidly than the dimensions of the cell, but the relative rates of change of nucleus and cell are constant.

The polyploid relationships discussed thus far are those which have been found in *induced* polyploids. In such forms there appears to be a close correlation between chromosome number, nuclear

size, and cell size. In the case of *natural* polyploids, however, body size, organ size, and cell size are, in general, not very different from their normal size in diploids. Gaiser (1927) found a general lack of uniform relation between number of chromosomes, cell size, organ size, and plant stature.

The nucleo-cytoplasmic ratio has been looked upon as an important factor in senescence. Botanists, as well as zoologists, have attributed senescence and rejuvenescence to changes in this relationship. Minot (1908) maintained that with age the nucleus of a cell decreases in size and that as a result there is a decrease in the nucleo-cytoplasmic ratio. Hertwig (1903), however, believed that physiological depression, senescence, and natural death are associated with an increase in the relative size of the nucleus. The results of Hartmann (1919a) on Cladocera also support Minot's theory. Meyer (1917) tried to measure the volume of the cytoplasm in the palisade cells of Tropaeolum in an attempt to find whether the nucleo-cytoplasmic ratio changes with age and discovered the ratio to be less in an old yellow leaf than in a young green one. In a study of senescence in the cells of the potato plant, Lutman (1925) found that senescence is accompanied by an increase in cell size without corresponding increase in nuclear size.

The nucleo-cytoplasmic ratio has often been thought to be important in the process of cell division, the ratio having been suggested as a factor in initiating cell division (Godlewski, 1910). Hertwig (1908) explained nuclear and cell division by his concept of "Kernplasma-Spannung," a "tension" created by an increasing disproportion between nuclear volume and cell volume, in favor of the nucleus, as the cell enlarges. Popoff (1908) also attributed cell division to a similar tension created in cells. Boveri (1905) believed the disproportion to be one of nuclear surface to cell volume. From measurements of nuclei and cells in the primary meristems of a number of the higher plants, Abele (1936) believes that cell division follows a disproportion in the ratio of nuclear surface to nuclear volume. Conklin (1912) in his work on cleavage stages in Crepidula denied the existence of a constant and self-regulatory nucleo-cytoplasmic ratio, holding rather that changes in this ratio are not causes of such cell activities as division but results of the metabolic processes by which such activities are brought about.

A number of physiological factors have been found to affect the nucleo-cytoplasmic ratio. Rautmann (1909) showed that there is a change in the ratio with a rise and fall of temperature in Paramaecium, although the ratio does not parallel the temperature changes exactly. Marcus' work (1906) also supports this conclusion. Hartmann (1919b), on the other hand, found that in cells of the plerome of Zea Mays and Phaseolus coccineus and of the dermatogen of Pisum sativum, subjected to a temperature of from 11.5°C. to 42°C., the nucleo-cytoplasmic ratio becomes less with an increase in tem-

perature. A similar lowering of the ratio is produced by X-ray treatment. Goodspeed (1929) shows this to be the case in leaves of *Nicotiana*, the seeds of which were irradiated.

The nucleo-cytoplasmic ratio is frequently a very variable one. Conklin (1912) contends that such a ratio does not hold even in the cells of the same tissue, for it varies with the different phases of mitosis. In cells of the cambium of *Pinus strobus*, Bailey (1920) found that the ratio of cell to nucleus varies from 12:1 in ray cell initials to 286:1 in tracheid initials. Klieneberger (1918), Ensign (1919), and Tischler (1924) have reported similar variability.

Surprisingly little work has been done on developing plant cells. Such questions as whether the nucleus increases in size as a cell vacuolates and whether the ratio of nucleus to cell changes during development remain unanswered.

MATERIALS AND METHODS .- Any study of the nucleo-cytoplasmic ratio in mature plant cells is necessarily a difficult one. The large central vacuole serves to press the cytoplasm in a thin film against the wall. If this cytoplasmic layer were of an equal thickness throughout, its volume might be determined fairly accurately; but such is probably not the case. The situation is very unlike that found in meristematic plant cells or in animal cells. There the cytoplasm fills the entire cell, and vacuoles, if present, are small and scattered throughout the protoplast. The cytoplasmic mass in such cells is that of the volume of the entire cell minus the nucleus, and its measurement may be attempted with some degree of accuracy. In mature plant cells, however, any attempt to determine the volume of the cytoplasm proper would be inaccurate and of little value. For this reason the ratio of nucleus to the entire cell volume, rather than to that of the cytoplasm only, has been determined. This has been termed the cytonuclear ratio (Sinnott and Trombetta, 1936). If the vacuole is to be regarded as a part of the cytoplasm, this term would, of course, be synonymous with nucleo-cytoplasmic. In view of the sharp distinction between vacuole and cytoplasm in most mature plant cells, however, the term cytonuclear seems less ambiguous.

A criticism often made against studies of the volume relations of nucleus to cell is that it is hard to find material having nuclei and cells which may be measured accurately and also possessing a wide range in cell size. Measurement of cell volumes does present a difficult problem. A fairly close approximation to accuracy can be made, however, if the cells are spherical or of a simple geometric form like a cylinder. An even greater difficulty is often found in measurement of nuclear volumes. If the nuclei are spherical and suspended in the center of a cell, as they are in meristematic tissue, a fairly accurate determination of their volumes may be obtained; but if they are pressed against the wall, as in vacuolate cells, and thus become considerably flattened, the problem of obtaining volume measurements is a serious one. If these flattened nuclei are relatively symmetrical, dependable values may usually be obtained, but if they are irregular, an attempt to determine their volumes is practically impossible.

Because of these difficulties, a careful search was made for suitable material, having considerable range in cell size and fairly regular cells and nuclei. A variety of tissues was used, but chiefly stem tips and root tips of a number of representative families of the flowering plants, as well as leaves of *Elodea*, and stem hairs of the tomato. The following species were used:

Allium Cepa L.

Bryophyllum calycinum Salisb.

Cucumis sativus L.

Cucurbita Pepo L., inbred lines

Line-China

Line-Connecticut Field

Line—Connecticut Field  $\times$  China

Line-Mammoth Tours

Line—Pumpkin

Line-Straight Neck

Line-Spoon

Line-46

Elodea canadensis Michx.

Fagopyrum esculentum Gaertn.

Freesia refracta Klatt.

Glycine Soja Sieb. and Zucca (G. Max Merr.)

Helianthus annuus L. (Dwarf)

Helianthus annuus L. (Tall)

Hippeastrum puniceum Urban

Ipomoea tricolor Cav.

Lagenaria vulgaris Ser.

Lilium regale Wilson

Lycopersicon esculentum Mill.

Phaseolus multiflorus Willd.

Pisum sativum L.

Tropaeolum maius (Dwarf)

Tropaeolum maius (Tall)

Zea Mays L.

The seed of varieties of *Cucumis sativus*, *Cucurbita Pepo*, and *Lagenaria vulgaris* was supplied by Professor Sinnott.

In the case of leaves of Elodea and stem hairs of the tomato, living material was studied directly. The stem tips and root tips, however, were killed and sectioned. A number of different fixatives were tried, among them Flemming's, Navashin's, Modified Carnoy's, and Formalin-acetic-alcohol, but the most uniformly satisfactory results were obtained with "CRAF" (the chrom-acetic-formaldehyde formula of Randolph, 1935), with which little or no shrinkage was found to occur. All the material was treated in exactly the same manner so as to be strictly comparable. It was embedded in paraffin. Sections were made of the stem tips to a distance of approximately 5-15 millimeters behind the meristem; of the root tips, approximately 5 millimeters in most cases, but where a complete developmental history was desired, to a distance of approximately 70-90 millimeters. Heidenhain's iron-alum haematoxylin proved to be the best stain for such a study. Essentially similar results were obtained from a study of living and of preserved material.

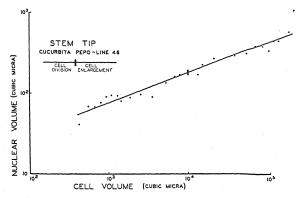

Fig. 1. Nuclear volume plotted against cell volume (both logarithmically) in cells of the stem tip of *Cucurbita Pepo* (Line 46).

Camera lucida drawings were made of the cells and nuclei; these drawings were measured and volumes calculated from them. A projected magnification of 1,700 was used. Meristematic cells of the root and stem tips are essentially isodiametric, and volumes were computed, from the average diameter, on the basis of a sphere. The results are thus probably somewhat too small but are comparable. The nuclei in such cells are spherical, and their volumes can thus be determined readily. Elongated, vacuolate cells of root and stem tips and of *Elodea* leaves are essentially cylindrical, and their volumes can be determined readily on this basis. In nuclei which have become somewhat flattened, if the polar diameter (a) and the equatorial diameter (b) are measured,

the volume may be computed by using the formula for a spheroid  $[4/3 \pi (a/2)^2, b/2]$ . If cells and nuclei as regular as possible in form are chosen, if measurements are made with care and in large numbers, and if the data are reasonably uniform and consistent, it is believed that the results obtained are dependable.

In an earlier paper (Sinnott and Trombetta, 1936), a method of analyzing the relationship between nucleus and cell was described similar to that proposed by Huxley (1932) for a study of heterogonic (allometric) growth. Here the logarithms of nuclear and of cell volumes are plotted against each other, the former on the y axis and the latter on the x axis. The graph in figure 1 illustrates this method. The points are from data given in table 1 in which nuclear and cell volumes for the growing point of

the stem of Line 46 of Cucurbita Pepo are shown. In this table the individual values for cell volume represent the average volume of successive cell-size classes, and the nuclear volumes represent the average nuclear values for the cells in this class (each average is one of 25–50 cells and nuclei). There is a considerable variability, doubtless due in part to difficulties of measurement, but the data fall into a rather narrow band to which a straight line may be fitted as shown in figure 1. Similar lines, without the points from which they have been determined, are shown in the other figures (fig. 2–13).

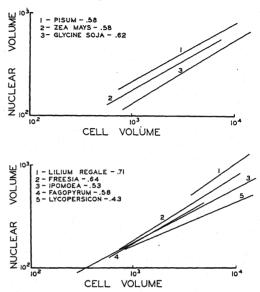

Fig. 6-7. Nuclear volume plotted against cell volume (both logarithmically) in cells of the root tips of various species. Measurements in cubic micra.

In the example used (table 1, fig. 1), the variation in cell size is great, from 426 to 174,800 cubic micra—a difference of 410 times. Nuclear variation is less, about 14 times. Evidently as cell size increases, nuclear size also increases but not as rapidly. In other words, with an increase in cell size, there is an increase in the cytonuclear ratio. That this is actually a case of growth of cells, not merely differences in cell size in the meristem itself, is indicated by the fact that only small cells are found in the active meristematic region. As one progresses back from the tip, the cells are increasingly larger. No uniform and constant relationship appears from a study of the table, but if the logarithms of nuclear and of cell volumes are plotted against each other, they fall along a straight line, indicating that the relative rate of change is constant and that a definite relationship can therefore be determined. This can be expressed by a constant derived from the slope of the line on the graph. Using the terminology of Huxley, x in this case is cell volume, y nuclear volume, b a constant denoting the value of y when x is unity, and k (or a in the terminology of Huxley and Teissier) the slope of the line, or the tangent of the

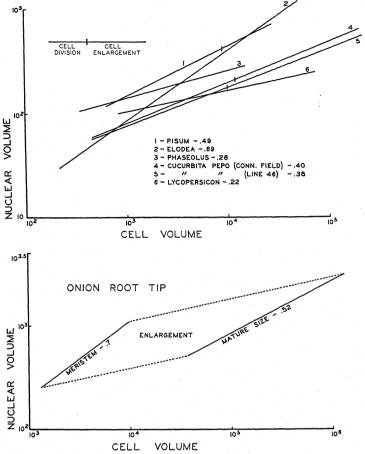

Fig. 8-9.—Fig. 8 (above). Nuclear volume plotted against cell volume (both logarithmically) in cells of the stem tips of various species. Measurements in cubic micra.—Fig. 9 (below). Nuclear volume plotted against cell volume in cells of the onion root tip.

angle which it makes with x. Thus  $y = bx^k$ , or log  $y = \log b + k \log x$ . The slope of this line in the present example, representing the value of the constant k, is about .38, which means that the rate of increase in nuclear volume (y) is about .38 as fast as that of cell volume (x). It is as though the nucleus were increasing at a compound interest rate of about 1 per cent and the cell at a rate of about 3 per cent. The arithmetic ratio between two such variables will evidently change progressively (as is shown in the table), since they are increasing at different rates. It is significant that it is the relationship between these rates, rather than any absolute values, which is constant. Even though the absolute cytonuclear ratio itself changes markedly, a definite relationship may therefore be determined between nuclear volume and cell volume. Such a method of analysis as employed here makes this relationship evident when a study of merely the absolute ratios does not do so.

RESULTS.—It was pointed out in the preliminary paper that these cytonuclear ratios are often specific and constant. In many cases the value of k approaches .67, indicating that the nucleus is growing about two-thirds as rapidly as the cell. Since the

surface of a cell increases as the square of its linear dimensions and its volume as the cube, and the surface thus increases two-thirds as fast as the volume, this result would indicate that the volume of the nucleus is keeping pace with the surface of the cell (or perhaps with the volume of cytoplasm in vacuolated plant cells). An examination of tables 2 and 3, and figures 1-13, however, shows that the value of k is often considerably above or below .67, although this value is near the average of all the determinations. In general, nuclear volume bears a definite relationship to cell volume, large cells having larger nuclei than small cells; but, as cell size increases, nuclear size does not increase as fast. A study of the data shows that there is a good deal of variation in the character of this cytonuclear ratio and suggests that no single explanation will suffice for all types. An analysis of these various types, however, should help to determine some of the factors involved.

Meristematic cells.—The root.—The k values obtained for root tip meristems of a number of plants are presented in table 2, and the graphs from which some typical ones have been determined are shown in figures 2–7. The values range from .39 in Cucu-

Pepo range from .45 in Pumpkin, to .74 in Mammoth Tours (fig. 2, 3, 4). In all these, the cell increases faster than the nucleus, but the relative rates vary considerably. Similarly the value of k for tall Tropaeolum is .43, but for the dwarf .74; and for tall Helianthus it is .82, but for the dwarf it is much lower, .59 (fig. 5). Evidently plant height is not related to these differences. Other root meristems studied show similar variation (fig. 6, 7). Since the general average of these values is approximately .6, it is evident that the nucleus tends to grow about two-thirds as rapidly as the cell and that as a result

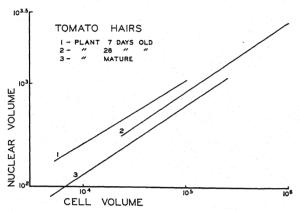

Fig. 13. Nuclear volume plotted against cell volume (both logarithmically) in cells of stem hairs of the tomato. Measurements in cubic micra.

the volume of the nucleus is keeping pace, in general, with the surface of the cell, though this relationship is subject to wide variability. The relationship in this tissue is essentially a true nucleo-cytoplasmic one, since meristematic cells are comparable to animal cells in being densely cytoplasmic, and any relationship of nucleus to cell is approximately one of nucleus to cytoplasm.

Significant differences appear in the level of the line in various species. This level (the value of b in the allometric formula) measures the difference in the absolute size relations of nucleus and cell at a given cell size. The cells of Pisum, for example, have relatively larger nuclei than cells of  $Zea\ Mays$ , or of  $Glycine\ Soja$  (fig. 6), though all the species have essentially the same k values.

The stem.—The k values obtained for stem tip meristems of a number of flowering plants are also presented in table 2, and the graphs constructed from the data are given in figures 8, 10, and 12. In nearly all the species, as in the root meristem, an increase in nuclear size accompanies an increase in cell size. The latter increases more rapidly, but the relative rates vary considerably, the values ranging from .69 in Elodea to .04 in tall Tropaeolum. Of significance in the stem meristem is the fact that the average value is considerably lower than that in the root. In three species (dwarf and tall Tropaeolum and Bryophyllum) the relative growth constants are very low (.09, .04, .12), showing that nuclear size

increases very much more slowly than cell size. In fact, there is little difference in the size of the nucleus in the entire meristem in these forms.

A comparison of the meristem cells in root and stem tips indicates that there is no marked difference in the absolute size of cell or nucleus in the two organs. In general, the roots have slightly larger cells and nuclei than the stems, but there are marked exceptions, such as dwarf *Helianthus*, where the nuclei and cells are larger in the stem.

Enlarging cells.—In view of the marked alterations undergone by plant cells as they pass from the meristematic condition to the much larger size and vacuolate condition at maturity, it is important to discover whether the cytonuclear ratio undergoes any change during this period. An attempt was made to determine this in several particularly favorable

types of material.

Three different phases of growth are generally recognized—the first, one of meristematic activity where cell division occurs; the second, one of enlargement, where there is a marked increase in size, accompanied by intake of water and development of a large vacuole; the third, one of differentiation, where the cell becomes mature. There are no sharp boundaries between these phases; cells in the upper region of the meristematic zone are undergoing enlargement, and cells undergoing enlargement have already begun to mature. This particular phase of the investigation is concerned mainly with the changes which take place during the phase of enlargement.

The difficulties encountered in such a study are serious. As the cell takes in a large quantity of water, a central vacuole is formed, filling most of it. This tends to flatten the nucleus (which until then has been suspended in the center of the cell) against the wall and makes it hard to measure accurately. Another difficulty is encountered in the preparation of unshrunken sections of root and stem tips in the region of cell enlargement. Several millimeters behind the tip, the cells are long, narrow, and very thinwalled. Fixation causes so much shrinkage and collapse of the walls that it proved impossible to obtain satisfactory material from which trustworthy measurements could be made in all types. Living material was more satisfactory at this stage and was studied in Elodea leaves and tomato hairs.

A study of this region of cell enlargement in a number of representative families of the flowering plants reveals three distinct types of cytonuclear behavior during development. In one type, the relationship of nucleus to cell found in the meristem is maintained throughout the active period of enlargement. Six such cases are shown in figure 8, and the k values for these species are presented in table 3. This has been found to occur in stem tips only. The approximate point at which the meristematic region ends and vacuolation begins was determined for only three of the six species, but from a study of the slides it is evident that meristematic activity ceases at approximately 10,000 cubic micra in all of them. The nucleus increases more slowly than the cell in all

cases, but the relative rates vary considerably. The significant feature is that the relationship of nucleus to cell found in the meristem persists throughout the period of vacuolation.

The second developmental type was found in root tips, stem tips, and leaves. Figures 9, 10, and 11 present typical examples. Here, the relationship of nucleus to cell which occurs in the meristem is not maintained throughout the period of enlargement. In the onion root tip (fig. 9), the meristematic phase of nuclear and cell growth is similar to that found in the other root tips described, the value of the relative growth constant being approximately .7. This relationship, however, is markedly altered during the period of active water absorption. Cell size increases enormously here, but nuclear size increases only slightly over that found in the meristem. When enlargement has ceased, a very similar size relation between cell and nucleus is again evident. In other words, during the period of active intake of water in the root, the k line in the meristem is shifted over markedly to the right and rises only a little. The change is mainly in the level of the line (the value of b in the formula). The slope of the line also changes slightly, for when the cells have reached their mature size, it is not so steep as in the meristem, the value of k being .52, indicating that the small cells of the meristem do not grow as much as the large ones. The fact that the k line in the meristem is shifted over progressively to the right suggests that for cells of different sizes but in the same stage of development, essentially the same cytonuclear relationship is probably maintained. In the development of an individual cell, however, from meristem size to maturity, the absolute ratio of nucleus to cell of course changes markedly. Cell size may increase as much as 100 times during the phase of water absorption; nuclear size increases only about 3 times at the most. A similar result was found in root tips of *Hippeastrum*.

It is assumed that as the k line shifts progressively to the right, during vacuolation, the relative sizes of cells remain constant, so that the smallest cells in the meristematic region are the smallest ones in the mature region. The question will naturally arise as to how one may be sure that such is the case since the history of individual cells was not followed. The subepidermal cell layer of the onion root tip offers good evidence on this point. This layer consists of alternating small and large cells which can be followed all the way back to the meristem. Each pair of cells arises by an unequal division in the meristem; by studying them, in succession, in a single row progressing back from the tip, one studies two cells which, although of different sizes, are of the same origin. Measurements show that even in the meristem the larger one has a larger nucleus than the smaller one, giving a k value of approximately .6 if a line is drawn through the two points. Successive measurements back from the tip indicate that the k line is shifted over progressively to the right and rises only a little, indicating a marked increase in cell size but only a slight one in nuclear size, precisely the situation postulated in the development of the root tip as a whole.

This same developmental type (the second) was also found in stems and leaves. Its occurrence in the stem is shown in figure 10. In dwarf Helianthus, as in the onion root tips, the k value in the meristem is .51, but in mature size the slope of the line decreases (.46), large cells growing more than small cells. That no nuclear size increase takes place during development is readily seen from the graph. Cell size increases considerably, but nuclear size remains the same as in the meristem. In tall Helianthus, nuclear size even drops a bit, although cell size increases enormously throughout development. A similar developmental history is found in Elodea leaves, where cell size increases considerably but nuclear size only slightly during enlargement (fig. 11). The slope of the line changes from .56 in the growing leaf to .75 in the mature one, indicating that the large cells do not grow as much as the small

The third developmental type was found only in stem tips of tall and dwarf Tropaeolum and in Bryo-phyllum (fig. 12). Here, as in the second type, the relationship of nucleus to cell found in the meristem fails to be maintained throughout the period of enlargement. As has already been pointed out for these three species, there is practically no nuclear growth in the meristem, the relative growth constants being .04 in tall Tropaeolum, .09 in dwarf, and .12 in Bryophyllum. Only when the end of mitotic activity is reached does nuclear size begin to increase, and from here on it shows a definite relationship with cell size. The constants are .63 for dwarf Tropaeolum, .72 tall, and .38 Bryophyllum.

These same general cytonuclear relationships are also manifest in a markedly different tissue, the stem hairs of the tomato (fig. 13). Multicellular hairs taken from the stem of a plant only 7 days old show a distinct relationship of nuclear and cell volumes, the relative growth constant being .62. The slope of the line is slightly different in hairs taken from a plant 28 days old and from a mature plant (.67 in each case). For three successive stages in plant development the cytonuclear ratio is thus essentially the same. A study of the level of the lines, however, shows a marked difference between the hairs of young and old plants, since in the latter the size of the nucleus for a given cell size is markedly lower. Hairs from a plant 28 days old are markedly smaller than those from a mature plant, indicating that the cells cut off by the apical meristem cell of the hair do not enlarge as much in the older plant. With maturity there appears to be a decrease in both cell size and nuclear size.

Discussion.—As a result of these studies on the cytonuclear ratio in plant cells, the conception of the relationship of nucleus to cell, as commonly found in the literature, evidently requires certain modifications. One major result of this investigation is very clear—the constancy which exists in the size relations of nucleus and cell is not between absolute values but rather between the relative rates of change of these structures during growth.

Thus the two conflicting views as to the cytonuclear relationship—that it is a constant and physiologically important one, or that it is extremely variable and therefore probably of little significance may be reconciled. Strasburger maintained that a constant size relation of nucleus to cell exists in the meristems of the higher plants, for he reports finding here a ratio of 2:3 between nuclear and cell diameters in a wide range of species. Obviously, however, such constancy as occurs cannot be one of absolute values, for the cytonuclear ratios are extremely variable when measured in absolute terms. It must rather be a constancy in relative rates of change. When volumes of meristematic nuclei and cells of a given species are compared, it is evident that there are marked differences in absolute cytonuclear values between large and small cells, but when they are plotted logarithmically, they fall along a straight line, showing a constancy of relationship. Large meristematic cells have relatively smaller nuclei in proportion to the size of the cell than small ones do. It is evident from such a study as this that the working-sphere of the nucleus is not a restricted one, but rather wide, as Bailey has pointed out.

The contrasted view of the cytonuclear ratio, as voiced by Bailey and others, regards it as an extremely variable one. This view is also open to criticism, for the variability is not random but follows a definite order with the result that a constancy does occur. Bailey found that the ratio of cell size to nuclear size in the elongated initials of the cambium of Pinus strobus varies greatly between large and small cells. If the method used in the present paper is applied, however, a relationship is found very

similar to that described here for meristematic cells. Although the cytonuclear ratio changes markedly in absolute terms, the relative rate of change is essentially constant. Similarly in studies of inanition in salamanders, Morgulis (1911) reports a wide variability in the ratio depending upon changes in the food supply. When the volumes of cells and nuclei reported by him are plotted logarithmically, however, the relative rate of change of nuclear and cell size is found to remain strikingly constant in spite of the fact that the absolute sizes of nuclei and cells decrease markedly during starvation and increase again when the animals are given food. Thus in many cases where the nucleo-cytoplasmic ratio has been reported as variable, a more precise analysis by the method here described will show that a constant relationship occurs, although it is between rates of change rather than absolute values.

The hypothesis of Boveri, Popoff, Hertwig, and others that a definite ratio of nucleus to cell is necessary before cell division will occur does not find support in these results. Mitosis occurs at very different ratios between these two variables in the same growing point, as a study of meristems of a number of species indicates. Extreme cytonuclear ratios, when the nucleus is either very large or very small in proportion to the size of the cell, may prevent mitosis, but in most meristems there is certainly no

constant ratio at which division occurs.

To find a physiological explanation for these definite cytonuclear relationships is a difficult task. As has already been pointed out (Sinnott and Trombetta, 1936), the frequency with which the relative size constant for nucleus to cell approaches .67 suggests that there may be a more definite relation than is apparent between volume of nucleus and of cytoplasm. If the thickness of the cytoplasmic layer remains constant in vacuolate cells of different size, then the area of the cell wall will be proportional to the volume of the cytoplasm which lines it. Since the surface of a sphere grows as the square of its linear dimensions and the volume as their cube, the surface of a spherical cell will increase two-thirds as fast as its volume; and since in many cells the volume of the nucleus has been shown to increase about two-thirds as fast as that of the cell, it is changing at the same rate as the surface of the cell. Thus if the volume of cytoplasm is proportional to the cell surface, the volume of the nucleus may be proportional to that of the cytoplasm, and there may actually be a constant nucleo-cytoplasmic ratio.

The marked differences in the way in which this ratio is manifest must also be explained. The changing relations of cell to nucleus which arise in so many species during the phase of cell vacuolation are perhaps an expression of differences in the water relations of these structures. The three developmental types which have been described above may possibly be explained by assuming differences between the nucleus and the rest of the cell in the absorption of water and dissolved materials. Differences in the ability of the cell to take in water by imbibition may be an important factor here, as may also differences in permeability between the nuclear and cytoplasmic membranes. Possibly a difference in osmotic concentration between cell sap and nuclear sap may be an important factor in regulating the amount of cell and nuclear enlargement. Variations in cell and nuclear growth in the meristematic region may also be due to variations in the rate of protein synthesis rather than of water absorption. These problems are important physiological ones but lie beyond the

scope of the present paper. The theory of senescence advanced by Minot appears to find some support from results here reported for tomato hairs. Between tomato plants 28 days old and mature ones, the size of cells in the multicellular hairs decreases considerably and of the nuclei even more, with a resulting decrease in the cytonuclear ratio. A mature plant is ordinarily less active metabolically than a young growing plant, as is indicated by the fact that assimilatory activity diminishes as a leaf ages (Willstätter and Stoll, 1918). There might well be a corresponding decrease in nuclear size with a decrease in metabolic activity. Some doubt is cast on this conclusion, however, by comparative measurements of nuclear volume in certain species. A direct indication of metabolic activity is sometimes provided by cell size itself, smaller cells being physiologically more active usually than larger ones, presumably because of their greater surface-volume ratio. Data from Pisum, Zea, and Glycine (fig. 6) show that the cell sizes for all three genera are essentially the same but that their nuclear sizes are different, Pisum being the largest, Zea next, and Glycine the smallest. If nuclear volume is a measure of metabolic activity, the three genera might be expected to differ in cell size as well.

As to whether changes in cell volume determine changes in the nucleus or vice versa cannot well be determined. In cases where nuclear volume is altered by changes in chromosome number, as in polyploidy, or in artificial nuclear doubling, cell volume follows the nuclear change. On the other hand, where the daughter cells from a given division are unlike, the nuclei, at first similar, soon accommodate themselves to the difference in cell volume. Nucleus and cytoplasm, of course, form a closely coordinated system, and it may be valueless to speculate as to which is the primary variable in development.

In view of the fact that the nucleus is the directive center of the cell and presumably controls its physiological, morphological, and genetical behavior, it seems highly important to discover how it exerts its influence. Most of the relations of nucleus

to cell are very difficult to discover, but the simpler quantitative ones, such as those reported here, can be measured with relative ease. A knowledge of these simpler relations is a first step toward an understanding of the more complex ones.

#### SUMMARY

The purpose of the investigation was twofold—to determine the quantitative relationship of nucleus to cell in meristematic plant cells and to show how this relationship is altered as these meristematic cells develop to their mature conditions.

Because of the difficulty involved in determining the nucleo-cytoplasmic ratio in mature, highly vacuolate plant cells, the relationship between nuclear volume and total cell volume (the cytonuclear ratio) was measured instead.

A variety of material was used, but chiefly stem tips and root tips of a number of representative families of the flowering plants, leaves of *Elodea*, and stem hairs of the tomato.

In most cases the nucleus increases in size less rapidly than the cell in cells of different sizes in the same stage of development, so that the actual cytonuclear ratio changes considerably. A constant relationship was found, however, between rates of change in size of the two structures, indicating a physiological interdependence between them.

In root meristems, the nuclear volume often increases about two-thirds as fast as the cell volume, thus keeping pace with the cell surface. This relationship is subject to wide variability, however. In stem meristems, the relative growth constants of nucleus to cell are lower than in the root.

In later development, where division has ceased but the cells are enlarging greatly, three distinct types of cytonuclear behavior were found. In one type, the relationship of nucleus to cell found in the meristem is maintained throughout the active period of enlargement. In the other two types, this relationship is greatly modified. Possible physiological explanations for these distinct types are suggested. The two conflicting views as to the cytonuclear relationship—that it is a constant and physiologically important one, or that it is an extremely variable one—may be reconciled by the results here reported.

A quantitative study of this type is the most direct method of approaching the important biological problem of the relation between nucleus and cell.

# PHYSIOLOGICAL DIFFERENTIATION IN ASTRAGALUS WITH REFERENCE TO SELENIUM <sup>1</sup>

Sam F. Trelease and Helen M. Trelease

Some species of Astragalus appear to be definite selenium indicators, occurring only on seleniferous soils and always containing selenium when collected in the field (Beath, Eppson, and Gilbert, 1935, 1939a, 1939b). Other species of Astragalus, however, are not limited to seleniferous soils. Even when growing on such soils in proximity to selenium-accumulating species, these are free from selenium or contain very low concentrations. Since two of the selenium indicators—Astragalus racemosus and Astragalus pattersonii—were found to be greatly

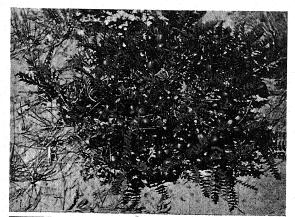

Fig. 1–2.—Fig. 1 (above). Astragalus crassicarpus Nutt. (prairie apple) growing on the Chugwater formation of the Triassic system about 7 miles east of Laramie, Wyoming. This species occurs on both seleniferous and non-seleniferous soils.—Fig. 2 (below). Astragalus racemosus Pursh growing on the Pierre formation of the Cretaceous system 15 miles south of Pierre, South Dakota. When air-dry, this specimen contained 3,920 ppm. of selenium. This species is a selenium indicator plant, apparently occurring only on seleniferous soils.

<sup>1</sup> Received for publication May 10, 1939. For general reviews of the selenium problem, see Trelease and Martin (1936), Beath (1937), and Moxon (1937). stimulated by selenium when cultivated in artificial media under controlled conditions, it was suggested that selenium may be an essential microtrophic element for the indicator plants (Trelease and Trelease, 1938).

In view of the apparent physiological differences within the genus Astragalus, it seemed of interest to study the influence of selenium on one of the non-indicator species when the plants were grown in solution and in sand cultures. For this purpose, Astragalus crassicarpus Nutt. was selected (fig. 1). One of the indicators, Astragalus racemosus Pursh (fig. 2), was included in the tests in order to secure comparable data on the two types of Astragalus.

MATERIALS AND METHODS.—Seeds of Astragalus crassicarpus, collected near Laramie, Wyoming, were kindly supplied by Prof. O. A. Beath; their selenium content, though undetermined, probably was low (Beath et al., 1935). The seeds of Astragalus racemosus were of the stock formerly used in culture studies; they were collected by us fifteen miles south of Pierre, South Dakota, and contained 2,125 ppm. of selenium. The culture methods were essentially the same as those previously employed (Trelease and Trelease, 1938). After being treated for twenty minutes with concentrated sulphuric acid, the seeds were soaked in tap water for three hours and then germinated in three-inch pots containing quartz sand. For the solution cultures, seedlings that were about three weeks old and 25 mm. high were removed from the sand and mounted in cork stoppers; each stopper bore five seedlings and fitted into a one-quart, jacketed Mason jar containing culture solution. During the early growth of the plants, the solutions were renewed every two weeks, and thereafter once a week.

For the sand cultures, ten seedlings were transplanted to three-gallon glazed earthenware jars plugged with coarse glass wool and filled with Ottawa silica sand ("flint shot"). The cultures were supplied with continuously renewed solution at the rate of one quart per day, by the method illustrated in figure 3 (Trelease and Thomson, 1935).

The plants were uniformly exposed to environmental conditions in the greenhouse. The period of illumination was extended by means of light from Mazda lamps (intensity about 250 foot-candles) from 5 to 10 p.m. The solution cultures of Astragalus racemosus were grown from December 4, 1938, to April 1, 1939. Those of Astragalus crassicarpus were also started on December 4 but were terminated earlier, on March 7, because of the withering and death of the plants in the highest concentration of selenium. The sand cultures grew from November 16, 1938, to April 7, 1939.

At the end of the growth period the plants in each jar were harvested and then weighed after having been dried for five hours in a forced-draft oven at 60°C. Analyses of samples for selenium were kindly made by Prof. O. A. Beath, H. F. Eppson, and C. S. Gilbert at the University of Wyoming. Some loss of selenium undoubtedly occurred during the drying of the plants, but this was considered to be unavoidable, since it was necessary to use dry weight as the criterion of growth.

All culture solutions contained the following concentrations of salts: .00072 m KH<sub>2</sub>PO<sub>4</sub>, .00048 m K<sub>2</sub>HPO<sub>4</sub>, .0040 m Ca(NO<sub>3</sub>)<sub>2</sub>, .0016 m MgSO<sub>4</sub>, .0016 m KNO<sub>3</sub>, .00053 m (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, .00004 m FeSO<sub>4</sub> (plus an equal concentration of K-citrate), and 15 cc. per liter of a stock solution (Trelease and Trelease, 1935) supplying the microtrophic elements Mn, B, Cu, Zn, Si, Al, I, Ni, Na, Li, As, and Co—of which only the first four are generally regarded as essential for higher plants.

Selenium was added as sodium selenite (Na<sub>2</sub> SeO<sub>3</sub>) in concentrations of 0.33, 1, 3, and 9 ppm. The S/Se ratio varied from 209 to 7.7 for the solutions containing from 0.33 to 9 ppm. of selenium, respectively; other ratios would have given somewhat different quantitative results (Trelease and Trelease, 1938). The initial pH value of the culture solutions was 6.4 (previously found favorable for Astragalus racemosus).

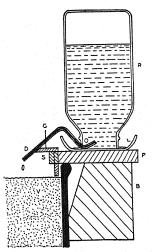

Fig. 3. Method of providing continuous renewal. Desired rate of flow is obtained by moving the apparatus to the right or left on the platform. After reservoir is refilled, the apparatus is reset by means of mark on tube D opposite guide nails G.

The conclusions drawn from this work are considered applicable only to the form of selenium used—selenite. The results might have been different with selenate (Hurd-Karrer, 1937) or with organic selenium obtained in water extracts of seleniferous plants (Beath, Eppson, and Gilbert, 1937).

GROWTH.—Table 1 and figures 4 and 5 show the influence of selenium (as selenite) on the dry yields of plants grown in solution cultures; table 2 gives the corresponding data for sand cultures.

The two species of Astragalus gave opposite responses to selenium. Astragalus racemosus was

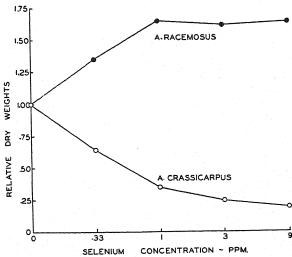

Fig. 4. Influence of selenium (as selenite) on the dry yields of plants grown in culture solutions. Astragalus racemosus is stimulated; Astragalus crassicarpus is poisoned.

greatly stimulated by selenium, whereas Astragalus crassicarpus was poisoned by it. In the sand cultures (table 2) the difference in the reaction of the two species was even more striking than in the solution

<sup>\*9</sup> ppm. Se for A. racemosus; 1 ppm. Se for A. crassicarpus (during first 12 days 9 ppm. was used).

cultures. The plants grew much more vigorously in the sand cultures, owing to better aeration of the roots and to continuous renewal of the culture solutions.

The results with Astragalus racemosus are in agreement with those previously reported for this species and for Astragalus pattersonii, and they suggest that selenium may be an essential microtrophic element for the development of various species of indicator plants.<sup>2</sup>

In being poisoned by relatively low concentrations of selenium (as selenite) in the culture solution, Astragalus crassicarpus resembles wheat, buckwheat, soy beans, tobacco, etc. (Martin, 1936; Hurd-Karrer, 1937; Martin and Trelease, 1938). Observations in the field have not yielded evidence for toxicity of selenium to this species, since neither native range plants nor crops have shown injury attributable to selenium in naturally occurring soils. These soils rarely contain more than about 10 ppm. of selenium, and much of this is in a form unavailable to any except selenium-indicator plants. Organic selenium, derived from native selenium-accumulating plants and often present in the soil, is much less toxic than inorganic selenite (Beath, Eppson, and Gilbert, 1937). We should therefore expect Astragalus crassicarpus to show a greater tolerance to organic selenium compounds than to the selenite used in the present tests.

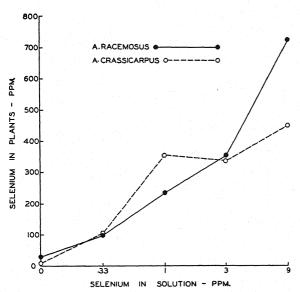

Fig. 6. Accumulation of selenium by Astragalus racemosus and by Astragalus crassicarpus growing in solution cultures.

Accumulation of selenium by the plants.—Analyses of the plants show no marked differences in the ability of the two species of *Astragalus* to absorb and accumulate selenium from solutions containing relatively low concentrations of sodium sele-

<sup>2</sup> It was not possible to deprive the controls entirely of selenium, since they received an initial supply from the seeds, which had a concentration of about 2,125 ppm.

nite (tables 1, 2, fig. 6). Astragalus racemosus, however, was able to accumulate considerably more selenium than Astragalus crassicarpus when the concentration in the solution was as high as 9 ppm. In an earlier study (Trelease and Trelease, 1938) it was found that Astragalus racemosus accumulated more than 3,000 ppm. of selenium when it grew in solutions containing 27 to 81 ppm. (as selenite)—concentrations that would be quickly lethal to Astragalus crassicarpus.

Although selenite is readily absorbed by Astragalus crassicarpus, as well as by wheat, buckwheat, tobacco, soy beans, etc. (Martin and Trelease, 1938), the pronounced susceptibility of these plants to selenium poisoning limits their accumulation of this element to a few hundred parts per million.

In contrast, the tolerance of Astragalus racemosus to selenium enables this species to accumulate very high concentrations. No symptoms of injury were observable when the selenium content was 726 ppm. (solution cultures) or 1,090 ppm. (sand cultures). In the study previously reported, marked reduction of growth did not occur until the selenium content of the plants exceeded 2,000 ppm. (Trelease and Trelease, 1938).

In the field, Astragalus racemosus shows no toxic symptoms even when it contains very high selenium concentrations. For example, the healthy plant shown in figure 2 contained 3,920 ppm. Well-developed specimens with a selenium content of 15,000 ppm. were obtained by Beath, Gilbert, and Eppson (1937). The high tolerance of plants in the field may depend upon the form of selenium present in the soil, since Beath and his co-workers have found that organic compounds of selenium, such as are obtained from water extracts of seleniferous plants, are more available and less toxic than the selenite used in our culture experiments.

Discussion.—The results of the present tests bring out a striking physiological differentiation within the genus Astragalus. This study, together with that previously reported (Trelease and Trelease, 1938), shows that Astragalus racemosus is greatly stimulated by selenium (as selenite) in the culture solution and possibly requires this element for its development. Astragalus crassicarpus, on the contrary, is not stimulated, but rather is poisoned by selenium in the nutrient solution—at least in concentrations of 0.33 ppm. (as selenite) or higher. The former species exhibits a high tolerance to selenium, withstanding a concentration of 81 ppm., but the latter is severely injured by 0.33 ppm. and is killed by 9 ppm.

These experiments seem to illustrate the physiological basis for the observations of Beath, Eppson, and Gilbert (1935, 1937, 1939a, 1939b) that Astragalus racemosus in the field is a selenium indicator, growing only on seleniferous soils and therefore useful for locating selenium areas. This species is distributed from North Dakota and Wyoming southward to Texas and New Mexico.

<sup>3</sup> The controls show low concentrations of selenium, possibly derived from the seeds.

Our culture experiments, showing that Astragalus crassicarpus is not benefited by selenium, are also in agreement with field observations that this species occurs on both non-seleniferous and seleniferous soils. It grows throughout the Great Plains area, from Manitoba and Montana to Texas and New Mexico, and in addition it extends eastward on to the non-seleniferous soils of Minnesota, Iowa, and Missouri.

In its physiological response to selenium, Astragalus racemosus appears to be like eighteen other indicator species of Astragalus and several species of Oonopsis, Xylorrhiza, and Stanleya (recently reported by Beath, Eppson, and Gilbert, 1939a, 1939b), whereas Astragalus crassicarpus seems to resemble alfalfa, wheat, buckwheat, tobacco, and soy beans, etc., as well as many other species of Astragalus, including A. carolinianus, A. diphysus, A. drummondii, A. flexuosus, A. missouriensis, etc.

Since the present experiments involved the use of sodium selenite (which all types of plants seem able to absorb), they failed to illustrate an important contrast brought out by the field studies of Beath, Gilbert, and Eppson (1935, 1937, 1939a, 1939b)—namely, that Astragalus racemosus is able to accumulate selenium from naturally occurring seleniferous soils, whereas Astragalus crassicarpus almost completely lacks this ability. These investigators have found that actively growing field plants of Astragalus racemosus always contain selenium.

The available analyses of Astragalus racemosus collected at different stages of development and on various types of soil are summarized in table 3

Table 3. Selenium contents of specimens of Astragalus racemosus collected at various stages of development and on various types of soils in the field (data from Moxon et al., 1938; Beath et al., 1937, 1939b).

<sup>&</sup>lt;sup>a</sup> These specimens may have lost selenium in drying (see Beath et al., 1939a).

(data from Beath et al., 1939b, and Moxon et al., 1938). In considering the few non-seleniferous samples recorded in the table, it should be borne in mind that the specimens may lose selenium on maturing and especially on drying. Beath et al. (1939a) state that although some of their samples have given

negative tests for selenium, subsequent analysis of plants from the same soil area at a time when new growth was starting has invariably resulted in obtaining positive tests for selenium; they cite a case in which Astragalus bisulcatus (a selenium accumulator) in the past-seeding stage showed only 3.5 ppm. of selenium, while the following spring a composite sample of plants from the same area showed 135 ppm.

Table 3 illustrates wide variation in the selenium content of Astragalus racemosus collected in the field. In a number of cases the selenium content exceeded 1,000 ppm., and in one case it reached 15,000 ppm.

In the field, Astragalus crassicarpus, in contrast to the indicator species, is free from selenium or contains mere traces, even when growing on selenium-bearing soils (Beath et al., 1935, 1939a).

Astragalus racemosus, like other selenium accumulators, is poisonous to livestock on the ranges, but Astragalus crassicarpus is non-toxic and edible (as is indicated by its common names: prairie apple, ground plum, buffalo bean, and buffalo pea).

A further contrast, and one of great economic significance, is that Astragalus racemosus differs from Astragalus crassicarpus in being one of the selenium converters and soil contaminators that change selenium into organic, water-soluble forms which, when returned to the soil, are readily available for absorption by all types of plants, including grasses and common farm crops (Beath, Eppson, and Gilbert, 1935, 1937).

Physiological differentiation of plant species with reference to the absorption and utilization of selenium provides an entirely new approach to the study of plant relationships, and it may have an important bearing on the investigation of the taxonomy and evolution of the species now generally included in the genus Astragalus (or grouped, as by Rydberg, 1932, into a number of closely related genera). Response to selenium may be used as a taxonomic character in the classification of Astragalus species. Considerable progress in this direction has already been made by Beath, Gilbert, and Eppson (1939a, 1939b).

## SUMMARY

Astragalus racemosus, growing in solution and sand cultures, was greatly stimulated by selenium (as selenite) in concentrations of from 0.33 to 9 ppm.; these tests confirm earlier experiments in suggesting that selenium may be an essential microtrophic element for this species of Astragalus.

In contrast, Astragalus crassicarpus was not stimulated; it was instead poisoned by selenium, being severely injured by a concentration as low as 0.33 ppm. (as selenite).

Astragalus racemosus, having a higher tolerance than Astragalus crassicarpus to selenium, was able to accumulate correspondingly higher concentrations of this element from solutions containing selenite.

The greenhouse tests of growth in artificial media confirm field observations in showing a physiological differentiation of *Astragalus* species into two groups: those which seem to require selenium for their development and so serve as indicators of seleniferous soil areas, and those which do not utilize selenium.

# THE GENERIC SEGREGATION OF THE SEQUOIAS <sup>1</sup>

#### J. T. Buchholz

The writer is thoroughly convinced that the Big Tree, Sequoia gigantea (Lindl.) Decn., and the Redwood, S. sempervirens (Lamb.) Endl., differ from each other to such an extent as to require their being segregated into separate genera. They differ by characters much more pronounced than those used to separate most genera within any of the families of conifers. That they should be looked upon as descendants of widely separated genera belonging to a larger group or family of world-wide distribution is abundantly evident from the study of paleobotany.

Throughout my investigations I had been under the impression that the results would lead to the recognition of Wellingtonia Lindl. (1853) as a valid generic name for the Big Tree, a name which has had some current use among European botanists. Wellingtonia, however, is a name applied by Meisner in 1840 to a dicotyledonous angiosperm, one of the Sabiaceae, in which usage it has been discarded, as a synonym, for the earlier Meliosma of Blume (1823). Wellingtonia Lindl. is therefore a later homonym, untenable as a generic name for the Big Tree, and to continue it in use is contrary to the current International Code of Botanical Nomenclature.

<sup>1</sup> Received for publication June 5, 1939.

Winslow considered the Big Tree a species of cypress, named it Taxodium Washingtonianum Winslow (1854), and expressed the wish that in the event that it should prove to belong to a distinct genus, it should be called Washingtonia californica. However, European botanists promptly referred the Big Tree to Sequoia Endl. where it has remained. Meanwhile, the name Washingtonia became established as a genus of palms, and it would be unfortunate to disturb it.

Other names under which the living Sequoias have been placed include Gigantabies, Senilis (1866) and Athrotaxis sensu Baillon (1892). The former was applied also to S. sempervirens, is a synonym of Sequoia Endl., and if considered equivalent to a generic name, was a superfluous name when published. Superfluous names have been rejected by the International Code of Botanical Nomenclature under Art. 16 and 60. Athrotaxis sensu Baillon is a broader concept which proposed the merger of the Sequoias with the Tasmanian genus Athrotaxis D. Don. The name Sequoia was first applied to the Redwood by Endlicher in 1847 and must remain as the generic name for this species. Thus it is clear that there is no generic name in the synonymy which

remains applicable to the Big Tree when segregated from Sequoia.

In the selection of an appropriate name for the Big Tree, it is very desirable that no word be selected which is wholly foreign to the names long in use. The name Sequoiadendron, which provides adequately for necessary generic distinction, does not wholly discard the long established name, Sequoia, and has obvious advantages in catalogues and indices. Furthermore, neither the resulting new binomial nor the continued use of the old botanical name will cause serious confusion.

While the Latin description given below is confined to the external diagnostic features which serve to separate the new genus Sequoiadendron from Sequoia, it seems desirable here to catalogue in a concise form all the more important external differences, some of which would have value only in distinguishing two species. While nearly any pair of these characters will serve to separate these two monotypic genera artificially, those in italics have generic significance. To these about 16 other histological and embryological differences are added, mostly of generic value and described elsewhere (Buchholz, 1938, 1939a, 1939b). These weigh heavily in confirming the conclusion that we are concerned here with two distinct genera. The most important generic differences are as follows:

Seed cones maturing and shedding seeds within year; ovuliferous scales becoming obliquely peltate with ovules and seeds attached in a single row near margin; buds scaly, foliage dimorphic in part taxoid with large leaves petioled, cotyledons usually 2. Sequoia Endlicher desc. emend.

Seed cones requiring two seasons to mature embryos and seeds and remaining alive and green for many years after maturity of seeds; ovuliferous scales becoming wedge-shaped, bearing two series of ovules and seeds; buds naked, foliage juniperoid, cotyledons usually 4. Sequoiadendron.

Sequoiadendron gen. nov.—Strobili polleniferi solitarii sessiles, in extremis ramulorum inter ramulos minimos lati. Strobili feminei plerumque in ramulis magnis subducentibus proximis ramulis ducentibus ramorum lateralium lati, squamae illorum 7–12 vel etiam plura ovula nuda erecta ferentes in serie duplici crescentiformi prope earum bases, eae spinis longis teretibus terminatae; ovula mox invertenda dum strobilus et ovula increscunt multiplicabilia strobilus ad 5–7 cm. longitudine crescit et biennium ut embryones maturescant requiritur. Strobili seminiferi virides manent et multos annos post maturitatem seminum persistunt. Embryones cum 3–5 cotyledonibus.

Arbor strobilifera gigantea cum gemmis nudis. Ramuli vestiti foliis parvis simplicibus imbricatis subulatis appressis vel non numquam divergentibus et spiraliter dispositis, bases rhomboides horum juvenem caulem tegentes; omnia folia unius speciei neque cum petiolis neque disticha divergentia.

Synonyms:

Steinhauera gigantea Ktze. ex Voss in Mitt. Deutsch. Dendrol. Ges. 16: 90 (1907).

Range: Western slope of the Sierra Nevada Mountains of California, associated with Sugar Pine, Fir, and Incense Cedar, in the California Arid Transition Zone, from the southern boundary of Placer County to the head of Deer Creek in Tulare County. Distributed in groves, widely separated in the north, but forming a series in a large nearly continuous area in the basins of the Kings, Kern and Tule Rivers, at altitudes between 4,500 and 5,500 feet in the north and between 5,500 and 6,500 feet or more in the south.

Type locality: Calaveras Grove, Calaveras County.

The external taxonomic characters are fully exemplified by specimens showing pollen cones, ovulate cones before pollination, and seed cones of previous years collected by the writer during April, 1936, at General Grant

<sup>2</sup> Nelson (John), under the pseudonym Senilis, wrote a book on Pinaceae (1866). He was an arboriculturist, living at Rinefield, Lymington, Hants. He renamed many of the conifers, following a system which he described as non-Linnean, according to which his binary names were compounded from categories much higher than a genus where there are not many forms in a sub-division, and from lower categories in groups embracing many species. His name "Gigantabies" is not a genus but in the higher category as a sub-division. This name applied equally to the two Sequoias, was a superfluous name when published, and has been declared illegitimate by the International Rules of Botanical Nomenclature (Art. 16 and 60). See also Jackson, B. D., p. 140, Guide to Lit. of Bot. 1881.

<sup>3</sup> The names given by Winslow are illegitimate names since they are nomina alternativa or eventualia (see Int. Rules of Bot. Nomenclature, 1935).

National Park. These have been deposited in the Herbarium of the University of Illinois, also similar specimens at Stanford University, the University of California, and elsewhere.

Summary of outstanding generic and specific differences

Sequoiadendron giganteum

Pollen cones 4-6 mm. long terminally sessile and solitary on small twigs.

Ovulate cones terminal on larger twigs resembling leaders of lateral branches, scales 25-40.

Cone scales bearing at pollination 3-12 or more erect ovules in double crescentic row.

Cone scales terminated by long terete spine, somewhat persistent.

Ovules becoming inverted during enlargement, to form single or double row of 3-9 seeds on surface of wedge-shaped scales.

Seed cone becoming 5-7 cm. long, cone axis very stout and woody; scales not easily broken off.

Seeds requiring two seasons for maturity of embryos.

Seed cone remaining green and attached to tree for many years after maturity of seeds.

Seeds 5-7 mm. long with 2 thin wings broader than body of seed.

Seeds yield ±200 per cone. Buds naked.

No vegetative reproduction.

Leaves all small, of only one kind, spirally imbricated, appressed or sometimes spreading, not petioled, revolute or distinctly ribbed, persisting and clothing the 2-5-year-old stem with rhomboidal areas.

Wood light (Sp. gr. 0.29) brittle, tending to fracture transversely. Sequoia sempervirens

Pollen cones stipitate.

Ovulate cones terminal on larger twigs, clothed with scale leaves. Scales 15-20.

Cone scale bearing at pollination 3-7 erect ovules in single arched row.

Cone scales terminated by long flattened spine, usually deciduous.

Ovules becoming inverted during enlargement, to form single row of 2-5 seeds near margin of obliquely shield-shaped scales.

Seed cone becoming 2-3 cm. long, cone axis relatively slender; scales of dry cone easily broken off.

Seeds requiring only one season for maturity of embryos.

Seed cone turning brown and shedding seeds at maturity.

Seeds 3-4.5 mm. long with 2 spongy wings not as broad as body of seed.

Seeds yield  $\pm 60$  per cone. Buds scaly.

Abundant vegetative reproduction.

Leaves dimorphic, the vigorous terminal shoots having small scale-like leaves, other branches bearing large scytheshaped, petioled leaves acute with prominent midrib and revolute margins, pale beneath and spreading in two ranks decurrent and clothing the 2-4-year-old stem with elongated cuneate areas.

Wood heavier (Sp. gr. 0.42) tough, tending to fracture lengthwise only.

Bark becoming 25-50 cm. thick, deeply furrowed or fluted in lobes up to 1 m. or more wide, dull reddish brown, tinged with purple on young trees.

Stem habit—becoming stout, branches turning upward at tip.

Becoming largest tree known.

Bark becoming 15-25 cm. thick, in ridges corresponding to ridges in trunk, up to 50 cm. or more wide; the bark furrowed with smaller ridges into long, narrow, fibrous scales often broken transversely, exposing a rich cinnamon red bark.

Stem habit—remaining more slender with horizontal or drooping branches.

Becoming tallest tree known.

There are several other differences, such as time of pollination—April–May vs. January–February—time of seed cone enlargement and of fertilization; differences which are also very marked where the two species are growing side by side in cultivation. The pollen grains of the Big Tree are  $23 \mu$  in diameter ( $\sigma = 1.5$ ), and those of the Redwood are  $33 \mu$  in diameter ( $\sigma = 2.6$ ) when expanded.

## Internal gametophytic differences

Sequoiadendron giganteum

Male gametophyte long and slender. Enlarged only at fertilization tube.

Female gametophyte alveolar in development throughout, similar to other conifers.

Usual condition of only one female gametophyte per ovule.

Relatively few (±20) archegonia, not all fully developed.

Jacket cells of archegonia none or relatively inconspicuous.

Megaspore membrane relatively thick, 2-3\(\frac{1}{2}\)\(\mu\).

Chromosomes—n = 11.

Sequoia sempervirens

Male gametophyte shorter, stouter. Widest at middle, sometimes branched or saccate.

Female gametophyte with free nuclei scattered throughout cytoplasm at both ends; alveolar only in central part.

Several female gametophytes per ovule in competition during development.

Very many (50-200) differentiated structures appearing as if archegonia, not all fully developed.

Abnormally large and irregularly scattered jacket cells.

Megaspore membrane relatively thin, less than 1  $\mu$ .

Chromosomes—n = 22.

#### Embryological differences

Sequoiadendron giganteum

Proembryo with free-nuclear stage.

Proembryo or ganized somewhat in tiers.

Prosuspensor present in embryo system.

Rosette cells and rosette embryos.

Sequoia sempervirens

Proembryo has no free nuclei.

Proembryo not organized in tiers.

No prosuspensor in embryo system.

No rosette embryos.

Cleavage polyembryony gives 10-12 or more embryos.

Cell volume average small.

Suspensor segments becoming very long and

slender.

Embryonal tubes successive in formation, replacing primary suspensors.

Embryo has 3, 4, or 5 cotyledons (mean = 3.7). Cleavage polyembryony usually gives 4 embryos.

Cell volume average large. Suspensor segments not so long. Much more stout.

Embryonal tubes nearly simultaneous and surrounding primary suspensor.

Embryo usually has 2 cotyledons.

There has been considerable discussion and some confusion as to the proper specific epithet for the Big Tree within the genus Sequoia. My selection of

Lindley's species name, giganteum, is based on unquestionable priority, and in combination with Sequoiadendron its use is legitimate.

## NOTES ON SOME MIDDLEWESTERN SPECIES OF BAPTISIA 1

## Mary Maxine Larisey

Baptisia australis (L.) R. Br. has for many years been the classical "dumping ground" for material collected in the middle west. There can be little doubt as to the true nature of B. australis, because for no other species is there such a wealth of literature, copiously illustrated. As originally described, it is a beautiful blue-flowered, large-leaved, simpleand erect-branched species of the eastern states and has been widely cultivated.

Throughout the middle west a blue-flowered. smaller-leaved, dichotomously and divaricately branched plant occurs in great abundance, and for many years this smaller type has been taken for B. australis. A comparison with authentic B. australis makes it very clear that the more western type is specifically distinct. Discovery of the type specimen of B. minor Lehm. in the Gray Herbarium indicates that this fact was recognized as early as 1827. In 1861 it was again described as B. texana by Buckley. But neither Lehmann's nor Buckley's name has ever received much attention. Not until 1932 when Small in Rydberg's "Flora of the Prairies and Plains of Central North America" described B. vespertina from Missouri, Kansas, and Texas was any widespread cognizance of its existence manifested. But Small's name, which has been recognized in the last few years, must go into synonomy along with B. texana. The true B. australis is confined to the area within Pennsylvania to southern Indiana, south to Virginia and Tennessee. It has been introduced in Vermont.

A list of the essential differences between the two species in question follows:

B. australis

B. minor

Plant 1.5 m. high.

Plant 0.6-1.2 m. high.

Stem stout, branches ascending.

Stem slender, branches divaricate.

<sup>1</sup> Received for publication June 15, 1939.

Leaflets obovate-lanceolate, 4-8 cm. long, 1.5-3 cm. broad, delicate.

Racemes 2-5 dm. long.

Mature pod oblong, slightly inflated, 3.5-4 cm. long, 1-1.5 cm. broad, abruptly beaked, stipe not exceeding the calyx.

Distributed along riverbanks, eastern states.

Leaflets obovate, 2-3.4 cm. long, 0.5-1 cm. broad, firm.

Racemes 1-2.5 (rarely 3.5) dm. long.

Mature pod oblong-elliptic, much inflated, 3.5-6 cm. long, 1.5-2.5 cm. broad, gradually beaked, stipe twice as long as the calyx.

Distributed on dry hills and prairies, middle western states.

A bibliographical treatment and description of *B. minor* follows:

B. minor Lehm. Ind. Semin. Hort. Hamb. 16. 1827; Linnaea 3: Litt. 119. 1828; Nov. Act. Nat. Cur. (Leop. Carol. Deutsch. Akad. Naturforsch.) Nova Acta 14: 803. 1828 (1829).

B. australis (L.) R. Br. var. β, Torr. & Gray, Fl. N. Am. 1: 385. 1840.

B. texana Buckl. in Proc. Acad. Nat. Sci. Phila. 13: 452. 1861; Proc. Acad. Nat. Sci. Phila. 14. 163. 1862.

B. vespertina Small ex Rydberg, Fl. Prairies & Plains Central N. Am. 456. 1932.

B. australis (L.) R. Br. var. minor Fernald, Rhodora 39: 312. 1937.

Plant 6-12 dm. high, glabrous throughout; stem slender, geniculate, widely dichotomously branched; leaves subsessile to short-petiolate, petioles 2-4 mm. long, leaflets obovate to obovate-cuneate, occasionally elliptic, apiculate, rarely obtuse or retuse, 2-3.4 cm. long, 0.5-1 cm. broad; stipules lanceolate to setaceous, 3-9 mm. long, persistent or caducous; racemes terminal, erect, compact; floral bracts cordate to ovate-lanceolate, 7-9 mm. long, caducous; pedicels stout, 5-7 mm. long; calyx-tube 9-10 mm. long, 6-8 mm. broad, upper lip subconnate, lobes of lower lip usually ovate, sometimes acute, 2-3 mm. long; corolla dull violet to deep blue, inner petals lighter, fre-

quently tinged with yellow, standard 2.5 cm. long, wings and keel 2.7–3 cm. long; mature pod oblong-elliptic, ligneous, much inflated, 3.5–6 cm. long, 1.5–2.5 cm. broad, tapering gradually into a short beak, long-stipitate, stipe twice as long as the calyx.

Distribution: dry hills, limestone glades and prairies, Missouri and Kansas, southwest to Texas; introduced

along railroads in Nebraska.

Citation of type and authentic specimens:

Kansas: along the road 4 mi. E. of South Haven, July 4, 1929, Rydberg & Imler 579 (NYB, authentic specimen of B. vespertina Small); camp ground, vicinity of Coldwater, July 6, 1929, Rydberg & Imler 676 (NYB, authentic specimen of B. vespertina Small).

Texas: northern Texas, May, Buckley (ANSP, TYPE

of B. texana Buckley).

Cultivated specimen: ex Hort. Hamb. "A." 1827, Lehmann (GH, TYPE).

The relatively frequent occurrence of hybridism, particularly in regions where the borders of the geographical ranges of some of the larger species overlap, has been the basis of much confusion within the genus. One of the most clearcut cases is that between B. minor Lehm. and B. leucophaea Nutt. in southwestern Missouri, Kansas, and Oklahoma. In general habit it more nearly resembles B. minor, but the flowers are bicolorous: the standard is blue as in B. minor, the wings and keel yellow as in B. leucophaea. Back-crosses to B. leucophaea are apparently common. Since this hybrid recurs in a number of localities in the vicinity of both parents with a fair degree of intermediacy between them, it seems advisable to propose a binomial and description:

 $\times$  B. bicolor Greenman & Larisey, hyb. nov.<sup>2</sup>

B. minor  $\times$  B. leucophaea.

Intermediate between B. minor and B. leucophaea: Plant less than 1 m. high; leaflets oblanceolate-spatulate or broadly obovate; racemes axillary, frequently flexuous, usually not secund; corolla bicolorous, standard purple, wings and keel cream or yellow.

Distribution: prairies, southwestern Missouri, Kansas,

and Oklahoma.

Citation of specimens:

Missouri: frequent on upland prairies, Webb City, Jasper Co., May 4, 1902, Palmer 127 (MBG, TYPE); rocky upland prairies near Webb City, Jasper Co., May 10, 1931, Palmer 39282 (MBG, GH, NYB).

Kansas: rich, black soil, stony prairie land 1 mi. S. W. of College, Riley Co., May 7, Bayliss (KA); about 2.5 mi. S. W. of Iron Mound, Saline Co., May 3, 1930, Hancin 215 (KA); hilltop near Manhattan, Riley Co., May 21,

1920, Herr 9 (KA).

Oklahoma: prairie near Tecumseh, April 22, 1932, Barkley 47 (MBG, UO); prairie 2 mi. E. of Norman, May 10, 1924, Bruner (USN); Fort Sill, Comanche Co., April 17, 1916, Clemens 11623 (GH); 6 mi. N. W. of Stillwater, May 18, 1931, Featherly (MBG); Ripley, July 17, 1931, Featherly (MBG); in open woodlands, S. Okla., near Interstate bridge, April 11, 1928, Nelson 10816 (MBG).

HENRY SHAW SCHOOL OF BOTANY, WASHINGTON UNIVERSITY, St. Louis, Missouri

<sup>2</sup> Inter minorem et leucophaeam media; herba vix 1 m. alta; foliola oblanceolato-spatulata vel anguste obovata; racemi axillares frequenter flexuosi plerumque non secundi; corolla bicolorata, vexillo purpureo, alis carinaque flavis vel gelvis.

# DEVELOPMENT OF THE EMBRYO SAC OF PLUMBAGELLA MICRANTHA 1

J. W. Boyes

Plumbagella Micrantha (Ledeb.) Spach is a small herbaceous annual, the only member of its genus, which grows in the mountains of Siberia. It is known also under the synonyms *Plumbago micrantha* Ledeb. and *Plumbaginella micrantha* Ledeb.

Since the extensive studies of Dahlgren (1915, 1916) on the Plumbaginaceae, interest in Plumbagella has grown. His work centered interest upon the method of embryo-sac development which he described for members of the sub-family Plumbagineae. The species studied included Ceratostigma plumbaginoides Bunge, Plumbago capensis Thunb., P. pulchella Boiss., P. zeylanica L. and Plumbagella micrantha (Ledeb.) Spach. The last-named species was the one most thoroughly investigated.

Dahlgren considered the development of the embryo sac in *Plumbagella micrantha* as much reduced. The macrospore mother cell functions as an embryosac mother cell. After the first meiotic division, a vacuole separates the two resulting nuclei. This division is followed only by the homoeotypic division, on completion of which the embryo sac is four-nucleate. The vacuole just mentioned, now somewhat

<sup>1</sup> Received for publication May 18, 1939.

enlarged, separates the two nuclei nearer one end of the embryo sac from the two nearer the other end. The nucleus nearest the chalazal end becomes the nucleus of the single antipodal cell; that nearest the micropyle becomes the nucleus of the egg; and the other two nuclei unite to form a diploid primary endosperm nucleus. Since only the two meiotic divisions seemed to be involved, this method of embryosac formation was of particular interest.

Haupt (1934) reinvestigated the development of the embryo sac in *Plumbago capensis* and agrees with Dahlgren's story for the same species up to the four-nucleate stage. The four nuclei, however, divide, and the daughter nuclei remain in pairs, one pair at each end and one pair at each side of the sac. One micropylar nucleus becomes the egg nucleus. Four nuclei, one from each pair, migrate to the center, where they fuse to form a tetraploid primary endosperm nucleus.

Dahlgren (1937) later concluded that embryo-sac development in *Plumbago zeylanica* and *Ceratostigma plumbaginoides* follows the sequence reported by Haupt for *Plumbago capensis*. He still considered, however, that his investigation of *Plumbagella*

was so thorough that development in that species cannot be the same as in *Plumbago*.

Fagerlind (1938a) has still more recently studied the development of the embryo sac of *Plumbagella*. The history outlined by him resembles, save in certain minor points, the usual method of development as described in the present paper. It is very different from that described by Dahlgren for this species.

My results have been briefly reported in a pre-

vious paper (Boyes, 1939).

This study has been conducted during the tenure of a Wisconsin Alumni Research Foundation Scholarship. The writer wishes to express his sincere thanks for the helpful criticism and kindly advice, given freely throughout the course of the investigation, by Dr. C. E. Allen.

MATERIALS AND METHODS.—With the help of Dr. George M. Reed of the Brooklyn Botanic Garden, to whom thanks are due, fruits of *Plumbagella micrantha* were obtained from the directors of the Botanical Gardens of Marburg, Copenhagen, Leyden, Bremen, and Palermo.

Seedlings were obtained from the fruits from Copenhagen and Leyden. Mature plants from the two sources were similar except that the stems of the Leyden plants were slightly reddish, whereas

those of Copenhagen plants were green.

The mature plants varied greatly in size at maturity, apparently being strongly influenced by environmental conditions prevailing in the greenhouse during the growth period. Those grown during the winter reached a height of only three or four inches in ordinary daylight. When artificial light was supplied at night, the plants grew to a height of a foot or slightly more but were of less erect habit. During July and August in ordinary daylight they reached a height of nine or ten inches.

Buds were cut from the inflorescences immediately before fixation. Pistils were removed for fixation from buds longer than about 2 mm.; smaller

buds were fixed entire.

Randolph's and Belling's modifications of the Navashin fixative were used most extensively for fixation. Both gave better results if the material was first dipped for 5–10 seconds in a 6:3:1 Carnoy solution. Fixation was aided also when materials in the fixative (whether or not prefixed in Carnoy's solution) were placed for a few minutes under a vacuum pump. Fixation in any of the Carnoy solutions (6:3:1, 3:1, and 2:1) alone was not consistently satisfactory. The Randolph modification in combination with prefixation with or without pumping treatment seemed superior to the Belling modification and was therefore chiefly used.

All material was dehydrated in alcohol, cleared in chloroform, imbedded in paraffin, sectioned at 15-20 microns, and stained in Heidenhain's ironalum haematoxylin. A few buds were stained with

Flemming's triple stain.

OBSERVATIONS.—As Dahlgren (1916) has reported, a single subepidermal archesporial cell gives rise to a parietal cell and a macrospore mother cell,

the latter of which functions as an embryo-sac mother cell.

The usual history.—As the nucleus of the macrospore mother cell prepares for the first meiotic division (fig. 1), the cell elongates and increases slightly in diameter. This nucleus is still in the early heterotypic prophases at the time that the meiotic divisions are completed in the microspore mother cells. The mother cell continues to enlarge slowly during the prophases until its relative size is ordinarily approximately that shown (after the completion of the heterotypic division) in figure 8. Very rarely, while still uninucleate, it becomes as large as or even larger than that shown in figure 2. Six chromosome pairs were clearly counted in the later prophases (fig. 3) and in the heterotypic equatorial plate (fig. 4). Usually the spindle (fig. 5, 7) lies near the center of the cell and parallel to its longer axis, but it may lie diagonally (fig. 6). Thus the two resulting nuclei, which pass into a brief interkinesis (fig. 8), commonly but not always lie in the long axis of the cell.

The two-nucleate condition is comparatively rare in my material, only eight cases having been observed. Fagerlind (1938a) did not see this stage. The nuclear reticulum does not completely reorganize, and no conspicuous vacuole is present between the two nuclei.

The second meiotic division follows quickly upon the first. The cell appears to be very little larger than at the time of the first division. The spindles of the second division commonly lie somewhat diagonal or at times nearly at right angles to the cell axis. Figure 10 shows in higher magnification the equatorial-plate stage seen in figure 9; figure 11 shows a late telophase stage in this division. The chromosomes are small and crowded.

Upon the completion of the second division, the resulting nuclei (fig. 12) often occupy positions approximately corresponding to the four points of a diamond. It is not uncommon to find them in a nearly linear arrangement (fig. 13). Rarely, all the nuclei lie closer to the chalazal end than is shown in figures 12 and 13. Such stages mark the beginning of the primary four-nucleate stage.

Soon after its organization, the micropylar nucleus is surrounded by a zone of dense cytoplasm (fig. 12, 13). This condition persists during the period of enlargement, which continues until this nucleus enters the prophases of the third division.

The three nuclei which lie closer to the chalazal end migrate toward that end (fig. 14). This movement is associated with a rapid elongation of the cell, and when the migration is nearly complete, conspicuous vacuoles appear (fig. 15). A large vacuole separates the three migrated nuclei from the micropylar one. A smaller vacuole usually appears between the micropylar nucleus and the micropylar end of the embryo sac. The three migrating nuclei continue their movement until they lie close together (fig. 16) at the chalazal end of the cell.

Fagerlind (1938a) points out that during the meiotic divisions the nuclei and spindles are dis-

Young secondary four-nucleate embryo sac; two nucleoli in one chalazal nucleus.—Fig. 33. A slightly older embryo sac with chalazal nuclei displaced toward the micropylar end.—Fig. 34. The usual secondary four-nucleate condition at the time of formation of the egg and antipodal cell.—Fig. 35. Enlarged embryo sac; fusion of the polar nuclei.—Fig. 36. Embryo sac at the time of the fusion of polar nuclei.—Fig. 37. Embryo sac; fusion of the polar nuclei completed.—Fig. 35-37 are × ca. 275; fig. 23, 25, 28, and 31-34 are × ca. 290; all others are × ca. 2330.

placed in the direction of the chalazal end of the embryo sac. Apparently he considers that this displacement, together with the later separation of the nucleus nearest the micropyle from the other three by a large vacuole, accounts for the location of three nuclei near the chalazal end of the sac. In general, there is some displacement of the nuclei and spindles as Fagerlind suggests; but as a rule it is not excessive and does not always occur (fig. 8, 12). My observations indicate that three of the four macrospore nuclei move almost to the chalazal end before the formation of a large central vacuole. The embryo sac is elongating at the time of formation of this large central vacuole, and both this elongation and the development of the vacuole probably contribute to the further separation of the chalazal nuclei from the micropylar nucleus.

The three chalazal nuclei now unite in various ways. In some cases two nuclei unite while a third lies very near (fig. 17-19). At other times, all three nuclei unite. In figure 21 all three nucleoli are still clearly visible, but the nuclear membranes in the planes of contact are disorganizing. It is probable that two of these nuclei have previously united. Figure 22 represents a more advanced stage of union. Meanwhile, as may be seen from figure 15, the micropylar nucleus has completed its growth and has entered the prophases of the third division. There is nothing to indicate that any of the uniting chalazal nuclei in these cases have advanced beyond the resting stage at this time.

Although chalazal nuclear unions may occur when the nuclei are in the resting condition, they take place as frequently in the prophases (fig. 20, 25, 26). A few unions, as will be seen later, are delayed until the metaphases, and even further delay is found in rare cases.

Very soon all nuclei have entered the prophases in preparation for the third nuclear division. The chalazal nuclei may now appear as three nuclei (comparatively rarely), as two (fig. 20), or most commonly as a single triploid nucleus (fig. 23, 24). In figure 23, the chalazal nucleus appears decidedly lobed as does also the single large nucleolus, but it is clear that there is only one nucleus. The nucleus shown in figure 24 gave a clear count of 18 chromosomes, two of which are in an adjacent section. Three satellite chromosomes are recognizable. In somatic equatorial plates (fig. 50), two satellite chromosomes are present. Thus it is clear that in the case illustrated by figure 24 the three chalazal nuclei have united into a single nucleus with 3 n (18)chromosomes. Figure 25 shows an embryo sac in which two chalazal nuclei (respectively 2 n and n) appear to be uniting in the prophases. The associated micropylar nucleus also is well advanced in the prophases.

The term "union" has been used in preference to "fusion" in the paragraphs preceding. When 18 chromosomes (3 n) are clearly present in one nucleus, there is no indication that the chromosomes of the component nuclei have become intermingled. Each component nucleus may still form a spindle of

its own (though it seems best to assume that only one spindle would be formed by this triploid nucleus). When a diploid nucleus is observed in the prophases, the chromosomes appear to be more or less distinctly separable into two groups. The nucleoli certainly unite in some cases. However, "fusion" would seem to imply a more intimate association of the nuclei than occurs here.

Nuclei in a more advanced stage of the third nuclear division are rarely encountered. The two chalazal nuclei (2 n and n) shown in figure 26 are in a late prophase after disappearance of the nucleoli. The unusually large size of these chromosomes is probably due to fixation in a Carnov solution. Figure 27 shows the chalazal complex in a very late prophase after the disappearance of the nuclear membranes. In this case it was possible to count 16 or 17 chromosomes on the section figured and one chromosome on an adjacent section. The chromosomes from one nucleus seem to be rather definitely grouped, whereas those from the other two nuclei are more closely associated. Apparently either two or three spindles would be involved in the ensuing division. The embryo sac shown in figure 28 has been reconstructed from three sections, and the chromosome groups found on the three sections are shown in figures 29 (the micropylar group) and 30 (the chalazal group). Figures 29 a and 30 b are from the same section. An examination of the groups shown in figures 30 a and b leads to the conclusion that 18 (3 n) chromosomes are in approximately the equatorial-plate stage, although no spindle fibers can be seen. (Compare figures 11 and 12, Fagerlind, 1938a.) It seems likely that two separate groups of chromosomes are participating in this chalazal division. Considering also stages like that shown in figure 24, where all the nuclei have united to form a single triploid nucleus, it seems very probable that one, two, or rarely three chalazal spindles may function in the third nuclear division.

Upon completion of this division, two triploid nuclei (fig. 34) are present at the chalazal end of the sac. In the majority of cases, each daughter nucleus contains only one nucleolus, and there is no indication that more than one spindle was involved. When two or three spindles are formed, they must commonly be so closely associated that the products unite in a single daughter nucleus at each pole of the spindle complex (fig. 31, 32). Each of the chalazal nuclei shown in figure 31 (after the third division) has two nucleoli, and the nucleus farther from the chalazal end is lobed. In several instances two nucleoli were observed in one of the chalazal nuclei (fig. 32). In one embryo sac, shown in figure 33, the division of the chalazal complex had probably involved two spindles and fusion of the daughter groups as previously described, but the chalazal division figure was located much farther than usual from the chalazal end of the sac. Chalazal nuclei with two nucleoli are never found at later stages, whence it appears that nucleolar fusion occurs in originally two-nucleolate nuclei.

Mature embryo sac with a synergid-like cell.—Fig. 48. Primary four-nucleate embryo sac showing two nuclei lagging at the time of migration.—Fig. 49. Advanced six-nucleate embryo sac with the cell next the egg enlarging.—Fig. 50. Somatic chromosomes from root tip cell; 2 n=12.—Fig. 51. Peculiar five-nucleate embryo sac.—Fig. 46, 47, and 49 are × ca. 275; fig. 38, 39, 41-45, 48, and 51 are × ca. 920; fig. 40 and 50 are × ca. 2330.

After the completion of nuclear reorganization, the nucleus nearest the micropyle becomes the nucleus of the egg. The triploid nucleus next the chalazal end becomes the nucleus of the single antipodal cell. The remaining triploid chalazal nucleus and the remaining haploid micropylar nucleus are the

polar nuclei (fig. 33, 34).

There follows a period of enlargement during which the embryo sac grows considerably (fig. 35; this, as well as fig. 36 and 37 are drawn on a much smaller scale than the preceding figures). The two polar nuclei, respectively haploid and triploid, approximate and meet, commonly in the neighborhood of the egg. At the time of union of the polar nuclei (fig. 36), one nucleus (presumably the triploid one) is usually larger than the other, and commonly more chromatic granules are observable within it. A tetraploid primary endosperm nucleus results from this fusion (fig. 37). This primary endosperm nucleus remains in its position during the enlargement of the embryo sac which precedes fertilization.

Exceptional method of development.—A six-nucleate embryo sac was observed in one of my earlier preparations. This was of particular interest at the time, because it appeared to be a clear case of an exception to Dahlgren's story. Twelve other six-nucleate embryo sacs have since been found, as well as five five-nucleate sacs. Cases which appear to be exceptions to the regular course of events have been found also at earlier stages. A careful study of these preparations indicates that there is an alternative method of embryo-sac development in Plumbagella

micrantha.

An attempt was made to estimate the frequency of the occurrence of this type of development. Such an attempt is somewhat complicated by the occurrence of degenerating embryo sacs. It is possible that some embryo sacs which would develop into sixnucleate sacs degenerate instead. If this possibility be excluded, a count of all embryo sacs which have reached a comparable stage indicates that this alternative method is followed in about 5 per cent (16 in

300) of the ovules.

The exact origin of the six-nucleate embryo sacs is not entirely clear. It is possible that they may result from the postponement of meiosis in certain mother cells which (before meiosis) enlarge beyond the size ordinarily observed at this stage. Figure 2 is a moderate example of such enlargement. In another instance, the mother cell had grown to be about twice the ordinary size but still contained only one nucleus. If meiosis were to occur in an unusually large cell, it is conceivable that the third nuclear division might be initiated before three nuclei had migrated to the chalazal end. A six-nucleate sac could then result as explained below. On the other hand, it is possible that such enlarged mother cells merely are destined to degenerate.

The development of a six-nucleate embryo sac may be traced with reasonable certainty back to the time of migration of nuclei toward the chalazal end. At this stage certain cases (fig. 38) are observed in which two nuclei have moved to the chalazal end and

have become separated from the third nucleus by a vacuole, this latter nucleus being itself separated by a vacuole from the micropylar nucleus. The extreme condition (fig. 39) is rare. It is, of course, probable that the third nucleus at times succeeds in completing its migration before the third nuclear division takes place. However, it is certain that in some cases this nucleus fails to reach the chalazal region before it divides.

Very rarely two of the migrating nuclei are left behind the first and become separated from it by a vacuole (fig. 48). Under such conditions it is conceivable that the two lagging nuclei might enter the third nuclear division either as one (after union) or as two nuclei. There would then be present, before the third nuclear division, one haploid micropylar nucleus; a diploid central nucleus (or two haploid nuclei) and a chalazal haploid nucleus. No clear cases of a situation such as this, however, have been observed.

In case the third nucleus lags behind the other two, development proceeds as follows. The two nuclei which have migrated to the chalazal end come to lie very close together, or unite. Figure 40 shows these two chalazal nuclei in prophase with their nucleoli in process of uniting; the third chalazal nucleus is still at some distance and in a much less advanced condition. In such a case three rather widely separated nuclei (fig. 41) pass into division (or 4 if the two approximated nuclei at the chalazal end have not united). The micropylar nucleus has n (6) chromosomes, the central nucleus n, and the chalazal nucleus (or nuclei) 2 n. Figure 42 shows the three nuclei in a late prophase after the disappearance of their membranes. Upon completion of this division, the resulting embryo sac has two nuclei at the chalazal end each with 2 n chromosomes: two centrally located nuclei, each with n; and two micropylar nuclei each with n chromosomes (fig.

Cell division now occurs (fig. 43, 44). The micropylar nucleus becomes the nucleus of the egg; the diploid chalazal nucleus becomes the nucleus of the antipodal cell; the two haploid nuclei nearest the egg lie in a third cell and the two remaining nuclei in a fourth cell. This fourth cell, adjacent to the antipodal cell, has one diploid nucleus and one haploid nucleus. It would seem that in such an embryo sac there are two potential primary endosperm cells.

It is difficult in view of the limited material available to trace the further history of these six-nucleate sacs. As the embryo sac grows, it appears that in some cases the cell adjacent to the antipodal cell enlarges while the cell next the egg remains small (fig. 45). In the five-nucleate embryo sac represented in figure 46 (drawn on a smaller scale than the preceding figures), it appears that the cell next the egg has remained small but its two nuclei have united, whereas the cell adjacent to the antipodal cell has greatly enlarged and its nuclei are arranged much as are the polar nuclei at a corresponding stage in an embryo sac of the more usual type.

A single case, probably representing the final stage in this series, is shown in figure 47. Here it appears that the egg has elongated and pushed inward beside the adjacent (originally two-nucleate) cell. The nuclei in the latter cell have united; the resultant uninucleate cell is to all appearances a synergid. The nuclei in the two-nucleate cell adjacent to the antipodal cell also have united to form an apparent primary endosperm nucleus which in this case would have 3 n chromosomes. The remnants of the antipodal cell are present at the chalazal end.

In one instance (fig. 49) the two-nucleate cell adjacent to the egg has enlarged, leaving the other two-nucleate cell next the antipodal small and undeveloped. In neither cell have the two nuclei as yet united. Figure 51 may represent a case in which the nuclei of the cell next the antipodal have united. Later stages have not been found, but it would seem that, when fully developed, there would be one diploid antipodal cell and adjacent to it a cell with 3 n chromosomes having the appearance of an antipodal cell

Although the method of origin of these six-nucleate embryo sacs seems reasonably clear, it is difficult to explain the cause of their appearance. In all but one case, stages involved in their formation were obtained from Copenhagen plants which appear to have a stronger tendency toward a development of this type. Furthermore, this type of development was found only in material collected during July and August, when greenhouse temperatures were high. It is not unlikely that high temperature may be one factor contributing to this peculiar development.

The five-nucleate embryo sac shown in figure 51 may represent a case in which two chalazal spindles were widely separated and so arranged that the chalazal chromosomes from one spindle united with the micropylar chromosomes from the other spindle. Three chalazal nuclei would result. As already mentioned, it may also be a stage in the later development of a six-nucleate embryo sac. The former interpretation seems preferable, since this sac is smaller than six-nucleate sacs seen at a corresponding stage.

Discussion.—The complete omission of the fourth nuclear division is the major difference between the method of embryo-sac development herein reported for Plumbagella and that found in Fritillaria (Bambacioni, 1928a), Lilium (Bambacioni, 1928b; Cooper, 1935) and Tulipa (Bambacioni and Giombini, 1930). In Plumbagella the migrated nuclei (usually three) after the second meiotic division lie very close to the chalazal end of the embryo sac. The migration of these nuclei is possibly more rapid in Plumbagella than in the liliaceous genera mentioned, since some or all of them unite before they enter the prophases of the third nuclear division, whereas in Fritillaria, Lilium, and Tulipa the chalazal prophase nuclei form separate spindles which then fuse.

Fagerlind (1938b) reports that at least one species of Statice has a tetrasporic tetrapolar 16-nucleate embryo sac of the Penaea type (see Schnarf,

1936). He is in agreement with Haupt (1934) in considering the tetrapolar 8-nucleate *Plumbago* type of embryo sac as having arisen from the *Penaea* type. Since both types occur in the Plumbaginaceae, and since they show remarkable similarity in organization, the conclusion is logical.

According to Fagerlind, Armeria bupleuroides (?) has the Fritillaria type of embryo-sac development. He suggests that the Plumbagella type (as now known) may have arisen from the Fritillaria type; he suggests also that either the Plumbagella type has arisen from the Plumbago type or the Plumbago type has been derived from the Plumbagella type. For reasons which will be discussed below, an origin of the Plumbagella type from the Fritillaria type seems the more likely.

The limited geographical distribution of Plumbagella, combined with the fact that there is only one isolated species, would suggest that this genus is an old one. Also to be considered is the annual habit of P. micrantha, whereas Plumbago and Ceratostigma species known to me are perennial. The growth habit of Plumbagella also is quite distinct from that of most members of related genera. In certain characters, as type of inflorescence and growth habit, Plumbagella resembles Ceratostigma; in others it resembles Plumbago. This combination of features may likewise be interpreted as indicating an earlier origin of Plumbagella.

Chromosome studies of Phillips (1938) and my own unpublished observations have shown that the chromosome number (n=6) and chromosome morphology of this species are different from those of species of Plumbago (n=7 or 14). Maury (1886) considered Statice to be the most ancient genus of the family. It is noteworthy, therefore, that the chromosomes of Plumbago species and that they resemble more closely the chromosomes of species of Statice.

In published accounts, the Plumbago type of embryo-sac formation is established for Plumbago capensis (Haupt, 1934; Fagerlind, 1938a), P. zeylanica and Ceratostigma plumbaginoides (Dahlgren, 1937; Fagerlind, 1938a). The writer has made observations (unpublished) on embryo-sac development in P. capensis, P. zeylanica, P. scandens, P. coccinea, Ceratostigma plumbaginoides, and C. Willmottianum. The embryo sacs of all these species develop as does the embryo sac of Plumbago capensis. In all, the embryo sac is short and wide, whereas that of Plumbagella is long and narrow. Thus far it appears that Plumbagella is unique in its method of embryo-sac development.

The early history of the exceptional six-nucleate embryo sacs of *Plumbagella* approaches that of the embryo sacs of *Plumbago* more closely than does the history of the typical 4-nucleate sacs. The later behavior of these 6-nucleate sacs might be expected to show some resemblances to the story in *Plumbago* if the two types of development are nearly related. But the later history is entirely different in the two cases

Plumbagella micrantha appears to be an old, isolated species with a considerable period of separate evolution. Embryo-sac development resembles the Fritillaria type also found in the family. The only available evidence fails to indicate any link between the Plumbagella and Plumbago types. It would seem best, therefore, to consider that the Plumbagella and the Plumbago types have arisen independently—the Plumbagella type from the Fritillaria type, the Plumbago type from the Penaea type.

Some tendencies toward reduction have been reported for the Fritillaria type. Maheshwari (1937) summarizes the situation in the following sentences: "Of the two chalazal nuclei of the secondary 4-nucleate stage, the innermost is usually in a degenerating condition right from the time of formation. In Fritillaria, it succeeds in going through a normal division, but in Lilium (Cooper, 1935) the division is more or less abortive. In Gagea this division commonly does not take place at all and the embryo sacs are 7-nucleate; finally there are some cases in G. ova where both the chalazal nuclei fail to divide and the mature embryo sac is therefore only 6-nucleate. All three conditions may also occur in the same plant, viz., Myricaria germanica (Frisendahl, 1912)." Maheshwari considers Clintonia borealis to have a reduced embryo sac of the Fritillaria type. Reduction in all these cases involves only chalazal nuclei, whereas in Plumbagella the number of both chalazal and micropylar nuclei is reduced.

Since Dahlgren (1916) has reported the Adoxa type for eleven different species among the Staticeae, it is only fair to accept his decision until more evidence is available.

It is suggested, therefore, that development according to the *Penaea* type is the primitive method of embryo-sac development in this family. The *Plumbago* type can be directly derived from this by the elimination of the last nuclear division. The *Adoxa* type could be derived from the *Penaea* type. The *Fritillaria* type may be considered a modifica-

tion of the *Penaea* type and the condition in *Plumbagella* a reduction of the *Fritillaria* type resulting from the elimination of the last (fourth) nuclear division.

The evidence for such a view is by no means conclusive. However, it is hoped that these suggestions may be helpful in considerations of the phylogenetic relationships of the various methods of embryo-sac development found in the Plumbaginaceae.

#### SUMMARY

The egg nucleus in *Plumbagella micrantha* is separated from the nucleus of the macrospore mother cell by three divisions.

In general, three of the macrospore nuclei (resulting from the second meiotic division) migrate to the chalazal end of the embryo sac where two or three may unite. If union is not completed before division, it is finally affected on the spindle or in the formation of the two daughter nuclei. One macrospore nucleus remains at the micropylar end and divides at the same time as the newly formed chalazal complex.

Of the four nuclei thus formed, one (with n chromosomes) becomes the nucleus of the egg; another (with 3 n chromosomes) becomes the nucleus of the single antipodal cell; and the remaining two nuclei (with n and 3 n chromosomes, respectively) unite to form a tetraploid primary endosperm nucleus.

The development of anomalous six-nucleate embryo sacs results if one of the three nuclei ordinarily migrating to the chalazal end remains behind and divides independently.

The Plumbagella and Plumbago types of embryosac formation are considered to have arisen sepa-

The *Plumbagella* type is considered to have arisen as a modification of the *Fritillaria* type.

# THE EFFECT OF VARIOUS COMPOUNDS UPON STRAIGHT GROWTH OF THE AVENA COLEOPTILE <sup>1</sup>

G. S. Avery, Jr., and G. B. Sargent

IN THE course of the past two years we have tested one hundred and eighty compounds for their growth stimulating ability, using the method described by Scheer (1937). They were selected from a wide variety of structural types, and many were previously known to be physiologically active.

In the past three years more than fifty growth stimulating compounds, other than those reported here for the first time, have been recorded by Kögl and associates (1935, Mitt. 14, 16), Zimmerman and Wilcoxon (1935), Zimmerman and Hitchcock (1937), Koepfli, Thimann, and Went (1938), etc. Different test methods were used by each group of workers. The compounds reported on were effective in concentrations ranging from a few gamma to more than one hundred milligrams per liter. Certain of them are known to occur in nature, though most are synthetic and have not been detected in living tissue. However, they all affect the sum total of the processes known as growth.

For each compound we have studied, a series of concentrations has been tested with a view to determining the stimulating range of such substances as were found physiologically active. The same kind of test organism has been used throughout, though we recognize that this test plant may not be equally sensitive to the many different classes of substances worked with.

Although many of the substances we are reporting on are growth stimulators or growth inhibitors, no mention should be made of them as "phytohormones," at least at this time. Some are synthetic compounds, and others are naturally occurring substances belonging definitely to chemical categories other than that in which the now-known hormones appear.

Materials and methods.—The sources of the compounds studied are given in tables 1, 2, and 3. Any significant estimation of impurities which might be present and thus affect the physiological activity of the compound is difficult. Although the compounds tested were as pure as could be readily obtained, there may have been impurities capable of playing a part in the growth response.

Substances of widely different molecular structure characterize the compounds chosen. These include aliphatic, aromatic and heterocyclic compounds, and some of their derivatives.

A wide range of dilutions was tested in most instances. The concentrations were chosen after the response in the preliminary tests had been ascertained.

In nearly all instances, the compounds were dissolved in distilled water, and all dilutions were made from the original solution with a minimum of

<sup>1</sup> Received for publication May 18, 1939.

delay. Substances very slightly soluble in water were first dissolved in a few drops of absolute ethyl alcohol and then added to water. Solutions of given dilutions were then mixed with equal parts of 3 per cent agar. (All agar was washed in daily changes of distilled water for a period of two weeks before use.) Following this, the agar dilutions were poured

into molds of  $10.7\times8\times1.5$  mm., and each of these was cut into six small blocks of equal size, ready for application to the test plant. The Avena test plants were cultured and tested in a laboratory maintained at 25°C., 85–90 per cent relative humidity, and illuminated only with phototropically inactive light.

The test procedure used was that described by Scheer (1937) and consisted, in brief, of decapitating the coleoptiles of four-day-old Avena seedlings (ca. 20-25 mm. in length) to 16 mm., measured from the coleoptilar node (which was marked by a fine line of lamp black in paraffin oil). The enclosed foliar leaf was withdrawn. At the end of forty minutes, the agar blocks were applied across the terminal ends of the coleoptile stumps (fig. 1). A minimum length of time was allowed to elapse between

the preparation of the agar blocks and their application to the test plants. In every set of tests plain 1.5 per cent agar blocks were applied to 12 test plants (controls) as the basis for estimating the growth stimulating qualities of the compound tested. All measurements were made with a small millimeter rule eight hours after the application of the agar blocks, and the length was recorded to the closest quarter millimeter.

The growth in length of the coleoptiles to which agar containing known amounts of a substance has been applied, over the controls (plain 1.5 per cent agar), is expressed in table 4 as millimeters increase over agar control. One or more check runs were made on most of the active substances. Although the magnitude of the response varied from test to test, the results were of the same order; variations at different test periods were comparable to those

reported by numerous others in the Avena curvature response.

About twenty separate tests of given dilutions, selected at random, were examined for probable error. The maximum found was  $\pm 0.1$  mm.

In addition to tests on straight growth, all compounds were tested for their ability to promote curvature in *Avena* in the usual Went test (coleoptile curvatures within 110 minutes after application of blocks). Results showed that ten were capable of bringing about *Avena* curvatures (see table 4), and the most active of these were re-tested by the "deseeded" method of Skoog (1937) (see table 5).

Compounds promoting straight growth of the avena coleoptile.—The derivatives of 3-indoleacetic acid and a-naphthyleneacetic acid show greater activity than do the other compounds tested, as shown in the histogram (fig. 2). The potassium salts of the various acids were prepared from the same samples of acids here tested; the close agreement (over the proportionality range) in the results of tests on acids and salts see tables 4 and 5) sug-

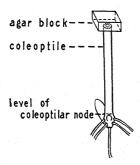

Fig. 1. Diagram of Avena seedling as test object in straight growth method (adapted from Scheer). The coleoptile is marked at the coleoptilar node, then decapitated to 16 mm. (the inclosed foliage leaf is withdrawn entirely). The agar block containing the substance to be tested is pressed gently over the entire cut surface of the coleoptile stump. Length is measured 8 hours after application of agar blocks (see text).

gests that the explanation for previous tests in which the potassium salts brought about a greater response than the acids (Avery, Burkholder, and Creighton, 1937; Scheer, 1937) lies in the fact that the salts were not prepared from the same samples of acids which had been used in their tests.

Amino acids, etc.—Of the amino acids, etc., tested and found active, tyrosine, tryptophane, p-acetylaminobenzoic acid, l-asparagine, l-valine, and xanthine produced the greatest response. This response, however, was not equal to that produced by certain other compounds, notably indoleacetic acid, naphthaleneacetic acid, and their derivatives.

The amino acids just mentioned were not equally effective at the same concentrations, as shown in figure 2 and table 4. The active range of *l*-valine is in the weaker concentrations while *d*-valine, *l*-phe-

<sup>2</sup> Delayed response.

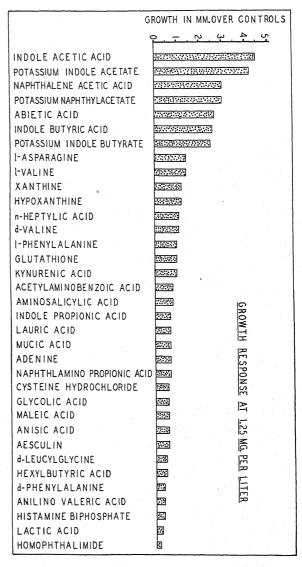

Fig. 2. Histogram showing straight growth response of the *Avena* coleoptile to the compounds listed in table 4, all compounds at a concentration of 1.25 milligrams per liter. The maximum response often came at higher concentrations, hence the histogram shows only comparative response at a given concentration.

nylalanine, and d-phenylalanine seem to promote over the whole range tested. The rest of the compounds promote mainly in the more concentrated range. The various types of responses, notably those of homophthalimide, l-valine and l-phenylalanine, indicate that, although all of them promote straight growth in Avena, they do so by very different means. It is possible that some of the compounds may be used by the coleoptile as accessory nutritive material.

Delayed response brought about by certain amino acids.—Agar made up with tryptophane and tyrosine and applied immediately to the test plants,

Table 4. Straight growth of the Avena coleoptile in response to different dilutions of various growth stimulating substances. All figures represent growth in mm. over agar controls. Measurements were made 8 hours after applying agar blocks.

brings about no response. However, if the agar containing given amounts of these compounds is allowed to stand at laboratory temperatures (in the dark) for varying lengths of time before application, chemical changes occur, and an active compound or compounds are produced; the possibility of enzymes in the agar seems precluded by its preparation—i.e., the long period of washing, autoclaving, and keeping sterile until use. Data bearing on this will be published later. Skoog (1937) reported that tryptophane and indole ethyl amine, in agar, were "activated" (chemically altered) upon contact with

plant tissue for a given period of time. The fact that a number of compounds included in table 3 gave inconsistent results from test to test suggests the desirability of examining response in relation to time in a considerable number of compounds.

Fatty acids.—Several fatty acids and substituted fatty acids were tested, and although none of them were quite as active as the indole compounds, they nevertheless caused substantial promotion of growth (table 4). n-Heptylic acid was the most active of the group tested. It promoted growth markedly in the lower concentrations used. The range of concen-

Table 5. Avena tests by Skoog's (1937) deseeded method, photographs after five hours. Curvatures by this test method are (in this laboratory) ca. 4 × as great as in the Went method. Each figure is the average curvature for two dozen test plants.

trations in which they promote growth is, for the most part, lower than that in which the amino acids are particularly effective.

Miscellaneous. — Many compounds of varied structure were tested; they cannot be classified under any of the above headings. Only 8 were active. The most active of this group of miscellaneous compounds was abietic acid which gave good promotion at 1.25 mg. per liter (table 4). Certain rather complex molecules were effective, and the compounds seem to have no particular relationship, structurally, with the known growth promoting substances reported here or by previous workers.

Compounds inhibiting straight growth of the avena coleoptile.—Our main object at this time is to make available to others the results of our inquiry into compounds capable of growth stimulation, but growth inhibiting substances should by no means be overlooked. Indeed, studies of the influence of growth depressing effects of certain types of compounds may well provide the key to the processes being influenced by growth stimulating substances.

Compounds found to be inhibiting are given in table 2, together with the dilutions tested. It is possible that other than growth depressing effects might be found if these substances were tested at different concentrations.

Compounds neither promoting nor inhibiting straight growth of the avena coleoptile.—Ninety-three of the compounds were neither growth promoting nor growth inhibiting in the dilutions tested (table 3), although twenty of this number gave inconsistent results.

DISCUSSION.—It is clear from the data presented that a very diverse group of substances possess the capacity to stimulate growth. Many of them do not have the configuration suggested as characteristic of "phytohormones" by Koepfli, Thimann, and Went (1938), though several of the compounds reported here show greater effectiveness in growth stimulation, as compared with 3-indoleacetic acid, than

<sup>3</sup> This statement is based on the consideration that if 3-indoleacetic acid at its optimum concentration gives 100 per cent response in straight growth, then all the compounds we list as active bring about at least 11 per cent of this response at their optimum concentration. Koepfli, Thimann, and Went, utilizing the pea test, con-

some of the compounds listed as active in their study. This raises several questions which can be only partly answered:

(1) Are the numerous compounds shown to be physiologically active in such tests as the ones used in this study, or any other, necessarily "phytohormones"? Went and Thimann's modification of Bayless and Starling's definition of a hormone is satisfactory for the purpose of discussion: "a substance which, being produced in any one part of the organism, is transferred to another part and there influences a specific physiological process." On the basis of this definition, only naturally occurring compounds may be regarded as hormones. Hence, until such substances as are dealt with here are demonstrated to be present in plant tissue, we must think of them only as "growth substances." They are, of course, physiologically akin to the naturally occurring hormones reported present in higher plants. The point presented here in connection with the delayed action of tryptophane and tyrosine (both known to occur abundantly in higher plants) suggests that many different naturally occurring hormones may be produced from amino acids (Avery, et al., unpublished except for abs.). The fact that growth substances produced from the amino acids are short-lived will make it difficult to isolate and identify them. Owing to the diversity of the active compounds, we can conclude little beyond what is already known-protoplasm responds to many different kinds of substances. However, the quantitative study presented here should clarify somewhat the physiological relationships of the many substances which might mistakenly be regarded as 'phytohormones."

(2) Do the active compounds have any molecular configuration in common? The more active substances do, but many of the less active, or even inhibitory compounds, are also structurally similar to the highly active ones.

(3) Why do not the compounds promoting straight growth cause curvature when tested by the curved-growth technique of Went? The lack of positive results in the curvature tests may be due to these sidered as active those compounds giving down to 2 per cent of the indole acetic acid response.

compounds having to undergo chemical alteration and to the fact that the physiologically active intermediate or end products have not been formed within the approximately two-hour-time lapse of the curvature test. If our tests had been made with the curved-growth technique only, most of the compounds would have been judged inactive. The greater length of time used in the straight growth technique would allow such changes to take place and time for the new compounds to take effect before the results are recorded. Failure to get the curved growth response with most compounds might also be attributed to the possibility that most compounds unilaterally applied in agar quickly become evenly distributed through the coleoptile, instead of remaining unilaterally distributed.

(4) Do compounds synthesized at different times, or by different methods, differ appreciably in their physiological effectiveness? Previously obtained data (Avery, Burkholder, and Creighton, 1937; Zimmerman and Hitchcock, 1937) make it appear, in the light of the present tests, that such may be the case for indoleacetic and indolebutyric acids and their potassium salts. In the present tests, the potassium salts were prepared from the same sample of acid tested, and the results were comparable in both the straight and curved growth tests.

Straight and curved growth tests were also made on two samples of naphthaleneacetic acid, one synthesized by Merck and Co., the other by Wilcoxon (1937). Both were obtained through the courtesy of P. W. Zimmerman. Although the physical appearance of the two preparations is different, their melting points are the same. The results of the straight growth tests show somewhat lower activity in the Wilcoxon preparation, whereas in the curved growth tests they appear approximately the same. Dr. Zimmerman reports by correspondence that with the green tissue test objects the two preparations were equally effective.

(5) The nature of the test object. The various test methods have their merits according to the

problem being investigated, and while this study has been primarily one on compounds, the kind of test object is a matter of importance which must not be entirely overlooked. The straight and curved growth Avena tests used here involve the use of etiolated Avena seedlings. The pea test of Went involves the use of etiolated Pisum seedlings (Went and Thimann, 1937). In contrast to these are the green tissue test objects used and discussed by Hitchcock and Zimmerman (1938, etc.), and others. Such test objects have been used in studies on the induction of roots as well as in other physiological responses. In the case of root induction the compounds being tested initiate cell division. However, cell elongation is involved in bringing about nastic and tropic responses, whether in green tissue or etiolated test objects.

In the case of indoleacetic acid, straight growth of the Avena coleoptile is promoted over a range in concentration of 20,000 fold. Other substances are less active in this particular test, most of them promoting growth over a much less extensive range of concentration. Hitchcock and Zimmerman note a range in concentration of 10,000 fold in which numerous substances are effective in inducing root formation in green tissue test objects.

#### SUMMARY

One hundred and eighty compounds of widely different molecular structure were tested for their ability to stimulate straight and curved growth of the Avena coleoptile. Aliphatic, aromatic, and heterocyclic compounds and some of their derivatives were tested. At the dilutions tested, 37 stimulated growth, 50 inhibited growth, and 93 were without apparent effect or gave inconsistent results. Only 10 of the active compounds—these previously well known—gave a clear-cut Avena curvature response.

# TWO NEW SPECIES OF RANUNCULUS § FLAMMULA 1

Lyman Benson and Annetta Carter

SINCE Latin descriptions are not considered to be desirable in a manual, the impending publication of volume 2 of Dr. L. R. Abrams' Illustrated Flora of the Pacific States makes necessary advance publication of two new species of Ranunculus, subgenus Euranunculus, section Flammula, as follows:

Ranunculus oresterus Benson, sp. nov. Practically glabrous terrestrial perennials; roots very numerous, filiform, 0.5-1 mm. in diameter, each root densely covered with hairs for its entire length; stems erect, not rooting adventitiously, about 1 dm. long and 1-1.5 mm. in diameter, 2-4-flowered, somewhat fistulose, glabrous except for long appressed stout hairs at the bases; radical leaf-blades simple, each broadest at the middle and tapering to the two acute ends, 3-4.5 cm. long by about 6-7 mm. broad, entire, glabrous, the petioles 2-4 cm. long, glabrous, markedly dilated, 1-3 mm. broad, the dilated leafbase perhaps forming almost the entire petiole, cauline leaves alternate or almost opposite, 2-5.5 cm. long by 2-8 mm. broad, sessile, some bracts opposite, sessile; pedicels 1.5 cm. long in flower and 2-5 cm. long in fruit, glabrous; sepals vellowish and petaloid, spreading, narrowly oblong, 3 mm. long by 1-1.5 mm. broad, glabrous, the length of the petals; petals 5, yellow, narrowly oblong, 3 mm. long by 1-1.5 mm. broad, the nectary-scale glabrous, apparently forming a pocket; stamens perhaps 5-10 (5 visible in the single flower); achenes 15-25 in a depressed-globose head 2-4 mm. long by 2.5-4 mm. in diameter, each achene obovoid or oblong-obovoid, 1-1.5 mm. long by 0.7-1 mm. dorsoventrally by 0.7-0.8 mm. laterally, smooth, glabrous, the margin with a distinct nerve, the achene-beak filiform, 0.4-0.6 mm. long, not curved; receptacle subglobose, 1 mm. long in flower and 1.5-2.5 mm. long in fruit, glabrous.

Herba terrestris perennis glabra; radicibus filiformibus pubescentibus; caulibus 1 dm. longis, 1-1.5 mm. diametro; foliis petiolatis integerrimis lanceolatis vel oblanceolatis 3-4.5 cm. longis, 6-7 mm. latis; sepalis 3 mm. longis, 1-1.5 mm. latis; petalis 5 luteis oblongis 3 mm. longis, 1-1.5 mm. latis; staminibus 5-10; carpellorum capitulo globoso 2-4 mm. longo, 2.5-4 mm. diametro; acheniis 15-25 obovatis laevibus 1-1.5 mm. longis; rostro filiformi 0.4-0.6 mm. longo.

In swales at the summit of the Blue Mountains, eastern Oregon, altitude 4,000 feet (fide Washington State College specimen), Baker City-Canyon City road. Known only from the type collection by

<sup>1</sup> Received for publication May 22, 1939. <sup>2</sup> As delimited by Benson. 1936. Amer. Jour. Bot. 23: 26-33, 169-176. William C. Cusick, June 4, 1902, No. 2800. Type specimen in the Dudley Herbarium, Stanford University, California, No. 96453. Isotypes: University of Oregon Herbarium, 3 sheets marked by the writer in 1932 with a square containing an x in its lower left corner; Washington State College Herbarium No. 10201; New York Botanical Garden.

Ranunculus oresterus is most closely related to R. alismaefolius Geyer and its varieties, particularly the variety montanus S. Wats. (Ranunculus calthaeflorus Greene.) It is to be most readily distinguished by (1) its pubescent roots (densely hairy their whole length), by (2) its remarkably small flower,<sup>3</sup> the petals not exceeding the sepals and being only 3 mm. long and 1–1.5 mm. broad, by (3) its small size, the stems being only 1 dm. long and 1–1.5 mm. in diameter and 2–4-flowered (R. alismaefolius var. alismellus A. Gray is almost as small, but is distinguished readily by ovate instead of elongate leaves and by ovate instead of narrowly oblong petals about 6 mm. long), and (4) by having only about 5 or 10 (5 visible in the flower) stamens.

Ranunculus alveolatus Carter, sp. nov. Glabrous to sparsely pubescent, semi-aquatic annual; roots filiform, numerous; stems many-branched from near the bases, semi-decumbent to erect, rooting adventitiously at the lower nodes, 12-30 cm. long and 1-1.5 mm. in diameter, fistulous; leaves alternate, the blades simple, ovate to ovate-lanceolate, 6-20 mm. long by 4-12 mm. broad, entire to slightly dentate, petioles of lower cauline leaves 30-85 mm. long, petioles of upper cauline leaves 6-35 mm. long; stipular leaf-bases membranous-margined, non-ciliate or slightly ciliate at the apices, 4-6 mm. long, conspicuous; pedicels 5-10 mm. long in flower and 10-40 mm. long in fruit; sepals 3, membranous-margined at the bases, broadly to obtusely ovate, 2-2.5 mm. long by 1-1.5 mm. broad, glabrous, persistent; petals 2-3, yellow, clawed, each blade ovate, 2-2.5 mm. long by 1 mm. broad, the nectary-scale a glabrous pocket, truncate; stamens 4-5, 1.25-1.5 mm. long; achenes 15-25 in a slightly elongated head 3-5 mm. long by 3-4 mm. in diameter, each achene oval, flattened, 1.5 mm. long by 1.25 mm. dorsoventrally by 0.5 mm. laterally, the surface alveolate, the margin obscure, the achene-beak obsolete; receptacle conical to narrowly ovate, 1 mm. long in flower and 2-3.5 mm. long by 1.25-1.5 mm. in diameter in fruit, glabrous.

Herba annua amphibia, glabra vel sparse pubescens; radices filiformes; caules 12-30 cm. longi,

<sup>3</sup> Unfortunately only one flower is available (the isotypes have abundant fruit, but no flowers), and, consequently, publication has been delayed ten years in hopes of obtaining more material.

1-1.5 mm. diametro, fistulosi, semidecumbentes vel erecti, ad basim versus multiramosi, ramis e nodis inferioribus radicantibus; folia alterna laminis ovatis ovato-lanceolatisve integerrimis vel paullo dentatis; foliorum inferiorum petioli 30-85 mm. longis, superiorum 6-35 mm. longis; laminae 6-20 mm. longae, 4-12 mm. latae; stipulae 4.6 mm. longae, conspicue membranaceo-marginatae eciliatae vel sparse ciliatae; pedicelli per anthesin 5-10 mm. longi, fructiferi 10-40 mm. longi; sepala 3, late obtuseque ovata, basi membranaceo-marginata 2-2.5 mm. longa, 1-1.5 mm. lata; petala 2-3, lutea unguiculata 2-2.5 mm. longa, laminis ovatis 1 mm. latis, squamulis nectariferis truncatis; stamina 4-5; carpellorum capitulum ovoideum, 3-5 mm. longum, 3-4 mm. latum; achenia ovalia complanata 1.5 mm. longa, diametro dorsoventraliter 1.25 mm., lateraliter 0.5 mm.; pericarpio alveolato, rostro obsoleto; receptaculum in fructu 2-2.5 mm. longum, 1.25-1.5 mm. latum.

Margins of ponds and marshy areas along small streams; Sierra Nevada foothills from Calaveras County to Placer County, California. The type specimen was collected between Fair Oaks and Folsom, 11/2 miles southeast of Orangevale, Sacramento County, April 25, 1937, Annetta Carter 1244 (Herbarium of the University of California No. 604080).

The following material from Dudley Herbarium, Stanford University (SU) and the Herbarium of the University of California (UC) has been examined. Placer County: Roseville, J. W. Congdon, April 2, 1894 (SU). Sacramento County: Folsom, Katherine Brandegee, May 8, 1907 (UC, in part); between Fair Oaks and Folsom, 11/2 miles southeast of Orangevale, Annetta Carter 821, May 12, 1935 (UC). Calaveras County: 7.5 miles west of San Andreas, John Thomas Howell 4707, April 13, 1930 (SU, UC).

The relationships of the two new species to other members of the section Flammula occurring in North America north of Mexico are shown by the following kev:

Perennials; achenes 1.2-2.5 mm. long, the beaks 0.3-1.5 mm. long or in one species 0.1-0.2 mm. long; petals 5-10, conspicuous and usually large, longer than the sepals, except in one species.

Subsection 1. FLAMMULAE. Achenes nearly beakless, the beaks, if present, 0.1-0.2 mm. long, the styles stout. 1. R. Flammula. Achenes distinctly beaked, the beaks 0.3-1.5 mm. or rarely only 0.2 mm. long.

Cauline leaves lanceolate, oblanceolate, or linear.

Roots glabrous in their mature portions; petals exceeding the sepals.

Leaves not dentate, sometimes serrulate or wavvmargined, usually entire.

Stems rooting at at least the lower nodes.

Achene beaks 0.3-0.5, rarely 0.7 mm. long; stems mostly less than 2.5 mm. in diame-1. R. Flammula vars.

Achene beaks 1 mm. long; stems mostly 5-10 2. R. ambigens. mm. in diameter.

Stems never rooting adventitiously.

3. R. alismaefolius.

Leaves (at least the radical) dentate.

5. R. hydrocharoides var.4

Roots densely pubescent their whole length; petals 5, not exceeding the sepals, narrowly oblong, 3 mm. long by 1-1.5 mm. broad; leaves entire; stems not rooting adventitiously.

4. R. oresterus.

Cauline leaves ovate or ovate-lanceolate.

Stems rooting at at least the lower nodes; flowers never in cymes.

Roots with no thickened storage parts.

Stems not fistulous or inflated, 1-1.5 mm. thick; cauline petiols sheathing the stem.

1. R. Flammula var.

Stems usually fistulous, 1-5 mm. thick, cauline petioles not sheathing the stem.

5. R. hydrocharoides.

<sup>4</sup> A variety the recombination of which is now in press. Based upon R. stolonifer Hemsl.

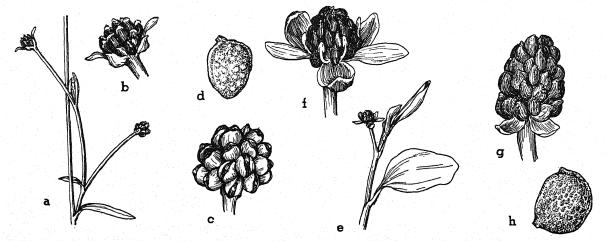

Fig. 1. Ranunculus.—Fig. a-d, R. pusillus: a, upper portion of plant showing sessile, linear-lanceolate leaves, X3; h, flower, ×9; c, hemispherical fruiting head, ×8; d, papillate achene, ×10.—Fig. e-f, R. alveolatus: e, upper portion of plant showing petiolate, ovate leaves,  $\times 2$ ; f, flower,  $\times 9$ ; g, fruiting head,  $\times 6$ ; h, alveolate achene,  $\times 10$ .

Roots each with a light-colored, fusiform storage thickening at the base. 6. R. Gormanii. Stems never rooting; flowers usually in cymes; roots each with a light-colored fusiform storage thickening at the base. 7. R. Populago. Annuals; achenes 0.6-1 or rarely 1.5 mm. long, the beaks 0.1-0.2 mm. long. Subsection 2. PUSILLI. Petals 5-9, large and conspicuous, about twice as long as the sepals; styles in anthesis 0.5 mm. long, filiform, deciduous in fruit; head of achenes hemispherical or ovoid. 8. R. oblongifolius. Petals 1-3, minute and inconspicuous, shorter than or equal to the sepals; styles in anthesis 0.1-0.2 mm.

Sepals 5; upper cauline leaves linear to lanceolate or oblanceolate or very narrowly elliptic, sessile;

achenes oblong-obovate, 0.6-1 mm. long, smooth, reticulate, or papillate, the units of the reticulate pattern perhaps 0.03 mm. in diameter when visible.

9. R. pusillus.

Sepals 3; upper cauline leaves ovate, petioled; achenes obovate, about 1.5 mm. long, reticulate, the units of the pattern about 0.1 mm. in diameter.

10. R. alveolatus.

## THE INHIBITION OF ROOT GROWTH BY AUXINS 1

James Bonner and J. B. Koepfli

It was shown by Kögl, Haagen-Smit, and Erxleben (1934) that solutions of crystalline auxin-a, or of indoleacetic acid greatly retard the growth of roots. This effect appears to be due to a specific property of auxins rather than to mere toxicity, since concentrations of indoleacetic acid as low as 0.005 mg. per liter suffice to give a detectable inhibitory effect upon the growth of wheat roots (Marmer, 1937).

It would seem paradoxical that auxins, which exert a promotive effect on the growth of stems, petioles, coleoptiles, etc., should, in concentrations of the same order of magnitude, exert exactly the reverse effect on the growth of roots. Numerous studies of the inhibition of root growth by auxins have already been made (Thimann, 1936; Went and Thimann, 1937). During the past two years a number of further experiments on the inhibition of root growth by auxins have been performed, and some of the results will be presented below.

MATERIALS AND METHODS.—The method used for the determination of the root inhibiting activity of a given substance was essentially that of Lane (1936). Avena grains were soaked for two hours in distilled water and were then allowed to germinate for 24 hours on moist filter paper in the dark at 25°C. At this time when the primary roots were 2-3 mm. long, comparable plants were selected, and the remainder discarded. Each substance to be tested for root inhibiting activity was used in concentrations decreasing by steps of 10 from 10-3 molal to concentrations sufficiently low (10-5 to 10<sup>-11</sup> molal) to be without effect. Four cc. of each solution to be tested were placed in a 10 cm. Petri dish containing a 7 cm. filter paper, and 10-15 of the selected 24-hour-old seedlings were placed in it.

<sup>1</sup> Received for publication May 1, 1939. Published as a report conducted with the aid of the Works Progress Administration, Official Project Number 165-036999, Work Project Number 6330-6989. The authors are deeply indebted to Philip Divirian for his able assistance with this work.

Each solution was always tested in duplicate (2 Petri dishes) and in one experiment 10 or more solutions were usually tested. After the germinating seeds had been placed in the experimental solutions, the dishes were returned to an incubator at 25°C. where they were allowed to remain for exactly 20 hours. At the end of this time they were removed, the length of the longest root of each plant measured, and mean values obtained for the growth in each solution.

This experimental technique gave very reproducible results from day to day. For example, the mean root growth of control plants growing for 20 hours in distilled water in experiments during successive days of February, 1937, were 14.5, 14.0, 14.0, 15.3, 13.9, 15.3, 14.6, 13.4, and 14.3 mm.

The chemical substances tested for root inhibiting activity were those used by Koepfli, Went, and Thimann (1938). Uracilacetic acid, prepared in these laboratories, was also tested.

PRELIMINARY EXPERIMENTS.—In figure 1 is given the relation between molal concentration of indoleacetic acid and root growth during the standard 20-hour experimental period, based on 5 experiments. In a solution of 10<sup>-3</sup> molal indoleacetic acid root growth was almost completely inhibited. With decreasing concentration of the substance, root growth increased, and concentrations below 10<sup>-11</sup> molal caused no measurable effect. No consistent increase of root growth in low concentrations of indoleacetic acid, such as those reported by Amlong (1936), Fiedler (1936), and Geiger-Huber and Burlet (1936), was observed in these experiments. In a number of experiments the lengths of the coleoptiles were also measured, and the results are included in figure 1. The application of indoleacetic acid to the roots of Avena seedlings under these conditions resulted only in decreases of coleoptile elongation, a result in agreement with those of Marmer (1937) and others.

Table 1. Decrease of inhibition of root growth with time in a solution initially 10-7 molal in indoleacetic acid, with simultaneous determination of auxin left in the solution.

Length of experimental period—hours	8	16	20	24	32	50	74
Growth in 10-7 m. indoleacetic acid, mm	0.5	3.1	8.1	14.5	24.0	39.8	73.0

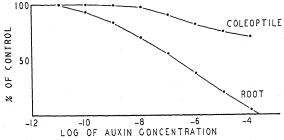

Fig. I. Relation of concentration of indoleacetic acid to inhibition of root and coleoptile growth of Avena seedlings.

If root growth under the above standard conditions be plotted against the log of the concentration of auxin, as is done in figure 1, a close approximation to a linear relation is obtained for root growth inhibitions between 80 and 20 per cent (as compared to control roots in water alone). The concentration of auxin needed to bring about an inhibition of 50 per cent can readily be obtained by interpolation. Thus from figure 1, the concentration of indoleacetic acid which inhibits root growth to just onehalf that obtained in the water controls is approximately  $3\times10^{-7}$  molal. Later in this paper the concentration effective in just causing a 50 per cent inhibition of root growth under these standard conditions will be used as one measure of the relative effectiveness of different auxins in root inhibition.

It was found that the length of the experimental period exerts a profound effect on the effectiveness of indoleacetic acid in causing root inhibition. For example, if a 44-hour experimental period was used, 100 times as high an initial concentration of indoleacetic acid was required to bring about 50 per cent inhibition as was needed to exert the same inhibiting effect over a 20-hour period. During the experimental period, therefore, the solution of indoleacetic acid becomes progressively less effective in inhibiting the growth of roots. This is in part attributable to the disappearance of indoleacetic acid from the solution, presumably due to its destruction by the roots. This was shown by experiments in which the decrease of root inhibition with time was measured and in which the auxin left in the inhibiting solution was simultaneously determined by the Avena test (table 1). However, at least one other factor also enters in e.g., the accumulation of root growth stimulating substances in the medium. This was demonstrated by experiments in which seedling Avena plants were allowed to grow in water or in indoleacetic acid solutions for 20 hours, after which they were transferred to fresh solutions. Fresh plants were then placed in the old solutions—i.e., the solutions in which plants had already grown for 20 hours. By comparison with control plants in fresh water it was found that these "old" solutions actually stimulated root growth by 15 to 30 per cent in different experiments. Both water control solutions and indoleacetic acid solutions which had once supported root growth appeared then to contain something promotive to root growth. This substance, or these substances, might appear to have diffused from the seedling plants during the first

experimental period. The promotive effect of used solutions could not be duplicated by balanced salt solutions, or balanced salt solutions plus sugar and/or various amino acids. It could, however, be duplicated by the addition of yeast extract or of crystalline vitamin  $B_1$  to fresh distilled water, as is shown in table 3. Although no further work has been done on this aspect of the problem, it seems possible that vitamin  $B_1$  or other substances promotive of root growth leach out of the seedling plant during the course of the root inhibition test.

THE RELATION BETWEEN CHEMICAL STRUCTURE AND ROOT INHIBITING ACTIVITY.-It is known that numerous organic acids possess auxin activity in promoting the growth of stems and coleoptiles (Haagen-Smit and Went, 1935; Kögl and Kostermans, 1935; Koepfli, Thimann, and Went, 1938), in the initiation of root primordia on cuttings (Thimann, 1935; Zimmerman and Wilcoxon, 1935), and in other plant growth responses. These organic acids have in common certain structural features which have been termed the "minimal structural requirements" for auxin activity (Koepfli, Thimann, and Went, 1938). The root inhibiting activities of several of these auxin "analogs" have been reported by Lane (1936), Marmer (1937), and others. During the present work, however, a large number of auxin analogs have been tested for root inhibiting activity under closely comparable conditions in order to determine whether or not the minimal structural requirements for other auxin activities hold also for root inhibition.

In table 4 the activities of 21 such analogs of indoleacetic acid are summarized. In the first column the concentration of each substance required to give 50 per cent inhibition of root growth is given. These values were obtained by interpolation as explained above. In the second column the activities are given relative to indoleacetic acid. The activities of these substances in the pea test (Went, 1934) have been determined by Koepfli, Thimann, and Went (1938). Reference to their paper shows that the activities of the different analogs in inhibiting the growth of roots are qualitatively correlated with the activities of the same substances in promoting the growth of pea stems. Thus with increasing length of fatty acid side chain the activity of the indole derivatives or of the phenyl derivatives decreases both in root inhibiting action and in stem growth promoting properties. Phenylacetic acid is less active than indoleacetic acid, and cyclohexaneacetic acid is almost completely inactive in both cases. Naphthalene and anthraceneacetic acid are highly active in both cases. With regard to steric factors also the chemical structures required for the two types of activities seem to be similar, as is shown by the high activity of ciscinnamic acid and the inactivity of trans-cinnamic acid as well as by the inactivity of a, a-dimethyl-

<sup>2</sup> For the sake of simplicity in the presentation, the term auxin "analog" will be used to refer to substances, other than auxins a and b or indoleacetic acid, possessing auxin activity in the *Avena* and/or pea tests.

toluic acid (as compared to phenylacetic or hydratropic acid. It seems justifiable to conclude that the chemical specificity of an auxin in relation to root inhibition is qualitatively closely similar to the chemical specificity of an auxin in relation to stem growth.

There are, however, quantitative differences between the relative activities of these analogs in different tests. This is shown in table 5, in which the

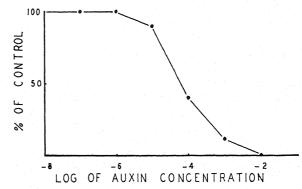

Fig. 2. Relation of concentration of phenylacetic acid to inhibition of root growth of Avena seedlings.

activities of indoleacetic acid and 3 of its analogs are given for the root inhibition test as well as for the Avena and pea tests. In the Avena test the activities are widely separated—e.g., cis-cinnamic acid is 1/1700 as active and phenylacetic acid 1/5000 as active as indoleacetic acid. In the pea test, on the contrary, these activities are much closer together, with cis-cinnamic acid equivalent to indoleacetic acid in activity and with phenylacetic acid only 10 times less active. The relative activities in root inhibition of these various auxin analogs as judged by the concentrations required for 50 per cent inhibition of root growth are intermediate between the relative activities of the same substances in the Avena test and in the pea test. Thus indoleacetic acid is 100 times more active than cis-cinnamic acid and 330 times more active than phenylacetic acid.

A comparison of the concentrations of these analogs needed to bring about a 50 per cent inhibition of root growth is, of course, purely arbitrary. It would also be of interest to compare the concentrations needed to give complete inhibition of root growth. In figure 2 is shown a curve of root growth plotted against molal concentration of inhibiting solution for phenylacetic acid. This curve whose shape is typical of those obtained for all the analogs tested with the exception of a-methyl-3-indoleacetic acid differs from that for indoleacetic acid itself in that (a) the slope of the linear portion is steeper, and (b) it is linear only over a limited range of root inhibitions and tends to approach the concentration axis asymptotically. No explanation for the differences of this curve from that for indoleacetic acid can be offered at present. It might be noted, however, that with the pea test also if growth response is plotted against the log of auxin concentration, the

<sup>&</sup>lt;sup>a</sup> Activities for Avena test taken from Went and Thimann (1937).

The fact that the curves for the analogs are not linear at high concentrations of analog makes a direct experimental determination of the analog concentration needed for complete inhibition difficult and inaccurate. It is possible, however, that this non-linearity is due to differences in secondary properties of each analog, for example in rate of penetration into the tissue. That such differences do exist has been shown by Went and White (1939). On this assumption, the concentration needed for complete or 100 per cent inhibition has been taken as the intercept on the concentration axis of the extrapolated linear portion of each curve. This has been done for all the substances listed in table 4. The results are of necessity crude, and only 4 of them are tabulated in table 5. The relative concentrations needed for complete inhibition, as obtained in this manner, are, however, strikingly similar. Ciscinnamic acid possesses an activity equal to and phenylacetic acid an activity only 4 times less than that of indoleacetic acid. Eight substances, indoleproprionic, indolebutyric, indolevaleric, a-methyl-3-indoleacetic, naphthaleneacetic, anthraceneacetic, atropic, and cis-cinnamic acids, possessed activities of 40 per cent or more of the activity of indoleacetic acid. Other analogs, however, such as phenylbutyric and phenylvaleric acid, are even by this criterion, 50-100 times less active than indoleacetic acid. The relative activities obtained in this arbitrary manner resemble closely those obtained for the pea test (D. Bonner, 1938).

RELATION OF pH TO ROOT INHIBITION.—It has been shown repeatedly (Dolk and Thimann, 1932; Bonner, 1934; Marmer, 1937; D. Bonner, 1938) that auxins are more effective as growth promoting

substances when present in the unionized state, and that because of this fact the pH of the solution in which the auxin is submitted to the plant exerts an influence on the subsequent growth response. In the pea test or in the Avena cylinder test (Bonner, 1933), for example, indoleacetic acid is much more active in bringing about growth if the solution is buffered at pH 4 than if the solution is buffered at pH 7. Experiments on the relation of pH to root inhibition by auxin were therefore performed for comparison with the earlier results on stem and coleoptile growth. McIlvain's standard buffer solution diluted 8-10 times was used. Preliminary experiments showed that the buffer itself, diluted thus, exerted no effect on root growth in the standard test between pH 4 and pH 7. Table 6 gives the result of one of

Table 6. Relation of pH of external medium to root inhibition by indoleacetic acid solutions.

	Concentration needed to give 50 per cent inhibition
Initial pH 3.80 } Final pH 4.10 }	3×10⁻7 molal
Initial pH 7.00 }	$1\times10^{-5}\mathrm{molal}$

a large number of experiments in which the effectiveness of indoleacetic acid buffered initially at pH 3.8 was compared with the effectiveness of the same auxin solution buffered at pH 7. It may be seen that at pH 7 approximately 30 times as high a concentration of indoleacetic acid was needed to bring about 50 per cent inhibition of root growth as was needed at pH 4. Just as in acid solution indoleacetic acid is more effective in promoting shoot or coleoptile elongation, so also in acid solution indoleacetic acid seems to be more effective in causing root inhibition.

It has been claimed that potassium or sodium salts of indoleacetic acid or other auxins are more effective than are the undissociated acids in the *Avena* test and in other growth tests (Avery, Burkholder, and Creighton, 1937; Zimmerman and Hitchcock, 1935). Although it has already been shown conclusively that this is not the case (D. Bonner, 1937), it is still worth mentioning that in root

inhibition also, when indoleacetic acid and potassium indoleacetate of equal purity are compared in buffered solutions, their activities are essentially identical. For this purpose freshly recrystallized samples of potassium indoleacetate and indoleacetic acid (from the same lot as that from which the salt was prepared) were used. In table 7 it may be seen that the two substances when made up in equimolar concentrations and buffered at pH 6.2 (the pH of the root) gave essentially identical root inhibitions. If the solutions were unbuffered, the potassium salt was somewhat less active than the acid.

On the nature of root inhibition.—One might next inquire as to whether the inhibition of root growth by auxins has any relation to the distribution or availability to the root of the substances essential to root growth. This problem can be attacked, since the chemical substances essential for the maintenance of root growth are now relatively well known (White, 1934; Bonner, 1937; Addicott and Bonner, 1938; Robbins and Schmidt, 1939). Cooper (1938), Went (1939a), and Stuart (1938) have shown that auxin gradients within the plant may influence the translocation both of other hormones and of sugars, etc. An attempt was therefore first made to discover whether or not the direction of the auxin gradient within the root exerts an influence upon root inhibition. Solutions of indoleacetic acid were applied either to the root tip alone, to the endosperm alone, or to the entire root and endosperm (as in the standard root inhibition test). Root growth was inhibited in all cases, although auxin applied at the base of the root was somewhat more effective than auxin applied at the root tip alone (table 8). It would seem unlikely, however, that the direction of auxin flow within the root is of any considerable importance in root inhibition.

Experiments of a different nature were designed to find out whether roots inhibited by auxin contained more or less of the materials needed for root growth than roots not inhibited by auxin. Root inhibition tests were carried out in the usual manner, using 10<sup>-7</sup> molal indoleacetic acid. After the 20 hours of the test 5 mm. tips were cut both from inhibited roots and from control roots, and these tips were placed in the solutions indicated in table 9. It may be seen from table 9 that in water alone neither the inhibited nor the control tips subsequently grew to any appreciable extent. In a balanced root solution (that used for the culture of isolated pea roots, Bonner and Addicott, 1937), however, the growth was more extensive and was somewhat larger in the case of the tips from roots previously inhibited by indoleacetic acid. The addition of sucrose to the mineral salt solution did not increase the final length of the roots but did increase the rapidity with which this final length was attained. Addition of vitamin B<sub>1</sub> to the medium resulted in a further increase of 50 per cent in the final length. In this case also the tips from inhibited roots grew only slightly more than the tips from non-inhibited roots. It seems necessary to conclude, therefore, that the materials essential for root growth are neither (a) accumulated in great excess in the extreme tips of inhibited roots nor (b) completely prevented from reaching the tips of inhibited roots. Similar experiments in which the whole root rather than a 5 mm. tip was excised after inhibition by auxin showed that the materials for root growth

Table 9. Growth of excised Avena root tips after treatment of the seedlings with or without indoleacetic acid. Seedlings placed in indoleacetic acid, 10-7 molal, or water for 20 hours.

		Growth in mm. after

do not accumulate in the base of the root during root inhibition.

In further experiments, root inhibition tests were carried out with Avena in the usual manner, but various other substances were added to the inhibiting medium. Table 10 shows that if vitamin  $B_1$  was

Table 10. Root inhibitions by auxin in the presence of vitamin B<sub>1</sub> and/or of sucrose in the medium. Indoleacetic acid 10<sup>-6</sup> molal in all cases.

Growth in percentage of water controls in:						
Indoleacetic acid alone	$32 \pm 0.7$					
Indoleacetic acid and vitamin B <sub>1</sub> 20 gamma/cc.	$49 \pm 2.7$					
Indoleacetic acid and sucrose 2 per cent	$45 \pm 0.9$					
Indoleacetic acid, sucrose and vitamin $B_1$	$51 \pm 1.6$					

added to the medium, the roots in auxin were inhibited somewhat less than if vitamin  $B_1$  was not added. A similar effect was brought about by 2 per cent sucrose. Other substances such as mineral salts, various amino acids, etc., were without effect. Thus, although root growth in the presence of indoleacetic acid may be limited to a slight extent by the available vitamin  $B_1$  and the available sugar, still the effect is not a major one, and it seems justifiable to conclude that the inhibition of root growth by auxins is not associated primarily with a deficit in any of these root growth factors.

A strong indication that the inhibition of root growth by auxin is attributable to a direct effect of the auxin rather than to an effect on the distribution of other necessary growth factors involved in root growth was also obtained by experiments with excised pea roots. The first experiments were carried out with root tips freshly excised from seedling plants and cultured aseptically with the technique and medium described elsewhere (Bonner and Addicott, 1937). It has been shown earlier that the freshly excised pea root tip contains an ample supply of vitamin B<sub>1</sub> and of nicotinic acid and hence is not limited in its growth by these substances. Such tips grow approximately 60 mm. during one week if supplied only sucrose and the requisite inorganic salts. In table 11 it is shown that the growth of these excised roots is inhibited by added indoleacetic acid just as is the growth of roots attached to the seedling plant. The addition of vitamin  $B_1$  to the culture medium exerted no effect on the growth of the control (without added indoleacetic acid) roots and but little effect on the inhibition by added indoleacetic acid. In these series a slight stimulation of root growth was found with auxin concentrations between  $10^{-8}$  and  $10^{-10}$  molal, in contrast to the results presented above for Avena roots, but in agreement with the finding of Fiedler (1936) and of Geiger-Huber and Burlet (1936) for isolated corn roots.

In other experiments isolated pea roots which had been one week in culture were subcultured (by removal of 10 mm. tips) into medium containing as accessory growth factors both vitamin  $B_1$  and nicotinic acid. It is known (Addicott and Bonner, 1938) that this combination of growth factors will allow unlimited rapid growth of the pea root, and it may be inferred, therefore, that such a medium supplies all the substances required for the growth of the pea root. Even in this medium, however, inhibition of root growth by applied auxin was readily obtained, 50 per cent inhibition of root growth being given by a solution approximately  $10^{-7}$  molal in indoleacetic acid.

It is known (Went, 1939b) that a pretreatment of pea stems with certain substances (themselves inactive in the pea test) greatly increases the sensitivity of these stems to subsequent treatment with indoleacetic acid. Thus pretreatment for 2 hours with gamma-phenylbutyric acid or cyclohexaneacetic acid may increase by as much as 100 times the subsequent curvature given by split pea stems immersed in indoleacetic acid of low concentration. Potassium anthraquinone sulfonate and sodium naphthol sulfonate pretreatments have been shown to increase the number of root primordia formed by cuttings in response to treatment with indoleacetic acid (Went, 1939a). A similar type of experiment was therefore carried out to determine whether or not the above substances also "facilitate" the action of indoleacetic acid in root inhibition. Avena seeds were germinated for 24 hours in the standard man-

Table 11. Inhibition by indoleacetic acid of the growth of isolated pea roots grown under sterile conditions in vitro. Mean of 4 experiments each with 20 roots at each concentration in each series.

ner, and they were then immersed for 2 hours either in water or in solutions (100 mgs. per liter) of phenylbutyric acid, potassium anthraquinone sulfonate, or sodium napthol sulfonate. After this 2-hour pretreatment the seedlings of each treatment were distributed into Petri dishes containing either water or indoleacetic acid in concentrations ranging from  $10^{-4}$  to  $10^{-10}$  molal. None of the pretreatments exerted any significant effect either on the subsequent growth of the roots in water or on their sensitivity to inhibition by indoleacetic acid. The action of auxins in root inhibition therefore differs from their action in the pea test or in root initiation in that the root inhibiting reaction is not facilitated by pretreatment with the above substances.

GENERAL DISCUSSION .- Auxins within suitable concentration ranges promote and are essential to the growth of many stems, petioles, the coleoptiles of grasses, etc. On the other hand, in similar concentration ranges they inhibit the growth of roots. These two seemingly diverse manifestations of physiological action are apparently both fundamental attributes of auxin activity. Thus among the analogs of indoleacetic acid those substances which possess great activity in promoting the growth of the Avena coleoptile possess great activity also in inhibiting the growth of roots. All the analogs active in the pea test are active (in the same order of decreasing activities) in root inhibition, and those analogs which are inactive in the pea test are also inactive in root inhibition. This means then that the chemical structure which a molecule must possess in order to exert growth activity on stem or coleoptile growth is closely similar to that which it must possess in order to be effective in auxin root inhibition. Increase in external pH also decreases the activity of auxin as a root inhibitor just as it decreases the activity of auxin in promoting the growth of stems or of coleoptiles.

These facts suggest strongly that auxin enters into an initial reaction which is common to root inhibition and to shoot elongation. This is essentially the hypothesis of Thimann (1935) who has suggested that auxin enters into some "master reaction" and that other properties of the particular tissue then determine what sort of an effect will be manifested.

It has been suggested above that the concentrations of auxin analogs needed to give complete inhibition of root growth may not be greatly different, at least in the cases of 9 of the more active substances. This might suggest that there is a definite number of reactive groups within the root and that if all of these are combined with an auxin, complete inhibition of root growth ensues. That is, the inhibition of root growth may depend on a stoichometric

relation between auxin and reacting tissue, just as has been shown to be the case (D. Bonner, 1938) in the response of pea stems to auxins.

Since the various nutritional factors needed for root growth are relatively well understood, an attempt has been made to offset auxin inhibition by a superabundance of the material needed for root development. This was possible, however, only to a very limited extent with the Avena root and impossible with isolated pea roots. Root growth was inhibited by auxin even in the presence of adequate supplies of all of the materials needed for growth of the pea root. It seems highly unlikely, therefore, that auxin inhibition of root growth is attributable to any kind of direct effect upon the availability of accessory root growth factors. Rather, it would seem necessary to assume that auxin acts directly on the root in some as yet obscure manner.

#### SUMMARY

The activities in inhibiting the growth of Avena seedling roots of 21 analogs of indoleacetic acid have been compared as to the concentrations needed to give 50 per cent inhibition of root growth. It is shown that the chemical specificity of the auxin inhibition of root growth is closely similar to the chemical specificity of auxin promotion of stem and coleoptile growth, since those substances such as indoleacetic acid, naphthaleneacetic acid, anthraceneacetic acid, phenylacetic acid, and cis-cinnamic acid which are relatively highly active in the Avena or pea test are also highly active in inhibiting root growth, while those substances such as cyclohexaneacetic and trans-cinnamic acid which are little active in promoting stem growth are also little active in inhibiting root growth. The relative activities in root inhibition of the 21 auxin analogs studied are similar to, but not identical with, relative activities of the same substances on stem growth.

Indoleacetic acid is more effective in inhibiting root growth in acid (pH 4) media than in media of higher alkalinity. The relation of pH to auxin activity resembles thus the relation known to exist between pH and auxin promotion of stem growth.

It is shown that the inhibiting effect of auxin on root growth cannot be offset to any significant effect by supplying the root with large excesses of the materials needed for root growth. The effect of auxin in root inhibition seems thus to be directly upon the root cells rather than upon the mobilization or transport of other growth substances.

# THE CAUSES OF SELF-STERILITY IN RYE 1

Margaret Landes

It is well known that rye is partially self-sterile (Brewbaker, 1926; Peterson, 1934; and others). While there is considerable variability, the average seed setting in the first year of selfing is under 10 per cent, but by selection individual plants which are highly self-fertile may be obtained (Peterson. 1934; Krasniuk, 1935). Following the work of East (1929) on Nicotiana, self-sterility in general has been regarded as due to the failure of pollen-tube growth through the action of a series of multiple alleles. Peterson (1934) interpreted data collected in an attempt to improve rye through selection of highly self-fertile lines in accordance with the general conceptions of East. Sears (1937) concluded that the general conception of self-sterility through the failure of pollen-tube growth is applicable to rye, since he found that few of the grains become empty. Nevertheless, Boyes and Thompson (1937), in connection with a study carried on for another purpose, found evidence of abnormalities in the development of the endosperm of rye which might be responsible for failure of seed setting after selfing. Many attempts have been made to obtain highly selffertile lines of rye, but none of these has been very successful. A number of these studies have been reviewed by Stout (1938).

The present study was undertaken to determine the frequency with which fertilization may occur in rye after self-pollination and whether or not selfsterility might be due to abnormal processes subse-

quent to fertilization.

METHODS.—Selfed ovaries of Prolific rye were fixed at various periods from 1 to 14 days after pollination. They were embedded, sectioned, and stained in the usual way. For comparison, ovaries of the same plants which had been crossed with quite unrelated plants of another variety were treated in the same way as the selfed ones. In addition, plants selected at random where pollination was open were harvested and examined for seed setting. Rye pollen from a number of plants was examined.

NORMAL DEVELOPMENT OF EMBRYO AND ENDO-SPERM OF RYE.—In the embryo at one day, two to four cells may be present. The endosperm develops rapidly, and thirty to forty free nuclei are present in the cytoplasm in the periphery of the embryo sac. Fifteen to twenty antipodal cells are present on the

ventral side (fig. 1).

By three days, the embryo is 6- to 10-celled and shaped like a pendant. Many free endosperm nuclei are present in the cytoplasm of the embryo sac lining and pocket (fig. 2).

There is considerable increase in the size of the sac at each stage examined. However, growth is most

<sup>1</sup> Received for publication April 3, 1939.

This problem was undertaken at the suggestion of Dr. W. P. Thompson, to whom I am greatly indebted for advice and constant assistance throughout the investigation.

rapid from three to nine days, for the embryo sac not only increases greatly in size but the endosperm becomes completely cellular. By five days, the embryo is 16- to 20-celled, and walls are forming in the endosperm of the pocket (fig. 3).

By seven days, the embryo is six or seven cells across and is about twice as long. The endosperm has increased greatly in size and is largely cellular except for areas at the center and antipodal side. Starch grains make their appearance on the ventral side toward the chalazal end. The antipodals have

disappeared.

A nine-day embryo is much like that at seven days except that it is larger and differentiation is beginning. The endosperm is completely cellular. The starch grains have increased in size and extend over a large area. The aleurone layer is clearly distin-

guishable.

At fourteen days the embryo is well advanced. Foliage leaves are differentiated; the coleoptile almost reaches around the growing point; epiblast and root tip are present, and the scutellum is elongated. In the endosperm, the cells on the ventral side are comparatively well filled with starch. On the dorsal side, the starch grains have crowded the nuclei to such an extent that they appear as dense irregular bodies. There is still an area near the embryo in which only a few small grains are present. The cells of the aleurone layer are well differentiated and well filled with aleurone grains. Part of the nucellus is still present.

Measurements were made of the embryo and endosperm at various stages of development, but rye varies so much in size from plant to plant that the results are considered insufficient to be of any value.

Development in selfed ovules and comparison with crossed.—Both selfed and crossed ovaries fall into four groups. In a small percentage, no embryo sac has been formed. In some of these there is a group of small cells at the center of the nucellus, and in others (fig. 4) a narrow strip of deeply staining material extends from the center toward the micropylar end. Presumably the breakdown occurs at or immediately after meiosis. At any rate, in these ovaries no megaspore enlarges to form an embryo sac. This form of breakdown appears to be widespread in rye, having been observed in 9 of 12 plants examined in two different years. It is, of course, not connected with selfing.

In the second group of ovaries, the embryo sac appears to be normal in every respect but remains unfertilized. At five days after pollination signs of degeneration begin to appear. Such ovaries are designated in the tables by the term "unfertilized."

In the third group the embryo sac is apparently formed but soon aborts. The cytoplasm becomes strongly granular and the antipodal nuclei small and

Normal strip through endosperm of crossed 7 da. embryo sac.—Fig. 1, 2, 3, 4, 8, ×85. Fig. 5, 6, 7, 9, 10, 11, 12, ×350.

dense or represented by stringy masses of chromatin. Even ovaries collected at one day have aborted to such an extent that only the degenerating antipodal nuclei can be recognized (fig. 5). After seven days the sac may be represented by a large empty space, or the whole ovary may collapse. Comparison of measurements of the aborted sacs with those which had not been fertilized shows that there was no appreciable difference in size.

In the last group some degree of development occurs. In many cases irregularities are found, but in all, development has at least proceeded beyond the normal three-day stage. Many of these developing ovules in which the irregularities are extreme may abort at later stages. These abnormalities affect the embryo less than the endosperm. They include patches of granular cytoplasm which may be large or small, very large or very small nuclei, nuclei with an unusually large number of nucleoli, stringy chromatin in varying amounts, failure of endosperm to fill the space formed by the expanded integuments, and cells with more than one nucleus.

The percentages of ovules of each of these four types (without embryo sacs, unfertilized, aborting

and developing) in selfed and crossed material for 1936 and 1937 are shown in table 1.

TABLE 1.

	Selfed				Crossed			
	1936		1937		1936		1937	
	%	No.	%	No.	%	No.	%	No.
Without embryo sac.	11	5	7	10	10	. 5	7	14
Unfertilized			47	68	17	9	13	26
Aborting	36	17	38	55	17	9	21	41
Developing	49	23	8	12	56	29	59	116
Total		47	4 .	145	4	52		197

The percentage of each of the four types of ovules is very similar in the crossed material in the two years, but in the selfed rve there is a marked difference in the second and fourth classes. In 1936 only 4 per cent of the ovules remained unfertilized, while failure occurred in 47 per cent of the ovules the following year. It is difficult to account for this difference, unless bud pollination occurred as described by East and Mangelsdorf (1926).

In comparing the selfed and crossed rye, the percentage of ovules failing to form embryo sacs in each of the two years is practically the same, as is, of course, to be expected. However, differences of varving degrees are present in the other classes. Only 4 per cent of the ovules selfed in 1936 remained unfertilized in comparison with 17 per cent in the crossed. At the same time, the percentage of developing ovules is relatively high in the selfed rye, being only 7 per cent less than the crossed. However, in 1937, the situation was reversed, and 47 per cent of the selfed ovules were unfertilized in contrast with 13 per cent of the crossed. In comparison with 59 per cent of developing ovules in the crossed rye, there are only 8 per cent in the selfed. The differences in the percentage of fertilized ovules in 1937 were apparently due to differences in pollen tube growth.

The most significant difference between selfed and crossed rye is the fact that the percentage of aborted ovules for both years is relatively twice as great in the selfed rye as in the crossed. While a certain amount of abortion in this group may be due to the same cause as the absence of embryo sacs, this will not account for the much greater degree which is present in the selfed rye. Abortion has in all cases progressed too far to determine whether the pollen tube had entered or fertilization had occurred. But presence of pollen tubes does not necessarily ensure fertilization, for Cooper, Brink, and Albrecht (1937) observed that certain well developed alfalfa ovules remained unfertilized even though pollen tubes were as numerous as in those which began development. At the same time, the higher incidence of abortion in the selfed rye sacs, than in the crossed indicates a relationship between the abortion and the entrance of the pollen tube.

A comparison of the developing selfed and crossed ovaries offers support for this view. While wide deviation from normal development occurs in both selfed and crossed rve, the frequency is higher in the selfed than in the crossed. Since irregularities in embryo and endosperm development are more marked at five days and later when growth is most rapid, no ovaries collected earlier than this are considered here. The numbers of developing ovules from five to fourteen days in 1936 were 8 selfed and 17 crossed, in 1937, 12 selfed and 101 crossed. Of these, 50 per cent of the selfed ovules (1936) and 16 per cent in 1937 were very abnormal in comparison with per cent and 9 percent of the crossed ovules.

It is interesting to note that the greatest number of these irregularities in the selfed rye is found in the 1936 group where the percentage of selfed ovules was highest (table 1), though there are none in the ovules from the same plants which were crossed. In 1937 when there were fewer developing selfed ovules, there are fewer irregularities. The same is

true to a lesser degree of the crossed rye.

The ovules included in this very abnormal group differ in the degree and type of irregularity present. In two seven-day selfed ovules and in one seven-day and one six-day crossed, the endosperm is largely confined to granular cytoplasm which lines the sac and fills the pocket. In the best sac, walls have formed in the lower part of the pocket (fig. 6). A few nuclei which are extremely dense in the crossed ovules, very large and "torpedo" shaped (fig. 7) in one of the selfed ovules and normal in the other, appear in the cytoplasm. In one selfed ovule the embryo is six-celled, but in the six-day crossed ovule it is many-celled. The embryo was not observed in either of the others. In one crossed seven-day ovule, the embryo is approximately twenty-celled, but the endosperm has aborted completely (fig. 8). In a nine-day selfed ovule there is a similar condition though there has been less growth, since the embryo is few celled. All that remains of the endosperm is a small patch of cytoplasm. A condition somewhat similar to this occurred where the sac increased greatly in size but collapsed at the center, leaving a small normal area at the micropylar and chalazal ends, with only cytoplasm between. This was observed in one selfed ovule and two crossed ones. There is still another type of abnormality which is less extreme than those described. The sac is larger and contains much cytoplasm of a granular nature. In it are scattered free nuclei and "islands" of normal cells (fig. 9). There are two selfed and four crossed ovules of this kind.

Irregularities of a lesser kind occur in most of the embryo sacs. These include areas of granular cytoplasm, stringy chromatin (fig. 10), which is usually found near the embryo, nuclei of unusually large size some of which contain seven or more nucleoli (fig. 11), and very small dense nuclei. In a few ovaries the endosperm fails to fill the expanded integuments. More than one kind of abnormality may be present in an embryo sac. A few ovules are free from any irregularity. In 1936, 25 per cent of the selfed ovules at five days and later were perfectly normal in comparison with 88 per cent of the crossed, and in 1937 none of the selfed were normal, though there were 28 per cent in the crossed ovules. A strip through the endosperm of a well developed seven-day crossed ovule is shown in figure 12.

Thus the irregularities which are present in selfed and crossed rye are alike in their nature and differ merely in the frequency of their occurrence. Whether the failure of formation of embryo sacs, the very early abortion of sacs, and the disturbances in endosperm development are due to the same cause is not known. But whatever the cause is, its effect is increased with selfing. In less than one-half of the aborted ovules there is stringy chromatin and other signs of abortion outside the ovule, but this seems to follow rather than cause the abortion of the sac. This is similar to the situation found by Cooper, Brink, and Albrecht (1937).

An examination of twenty-seven spikes from six plants selected at random from the same plot as those plants used in selfing and crossing in 1937 showed that under open pollination there was 54 per cent "seed" setting as compared with 59 per cent developing ovaries in the crossed rye. The percentage of seed setting under conditions of open pollination is somewhat lower than that observed by Krasniuk at Saratov who found an average of 58 per cent during the two-year period 1932-34. It is also lower than that found by Leith (1925) who reported one-third blind florets during a three-year test.

Among the "seeds" are a number which are abnormal in many ways. Some have ceased development at a very early stage, while others have varying degrees of endosperm irregularity which may be correlated with conditions found in the selfed and crossed rye embryo sacs. Some seeds have small shrunken areas which occur in the same region as non-cellular patches in the endosperm. Others have a shrunken constricted area at the center which corresponds to the embryo sacs which have normal areas at either end but collapse at the center. Only a few of the seeds are perfectly smooth.

In 1936, one crossed rye plant set 68 per cent seed, while two selfed rye plants averaged 27 per cent. The seed from the selfed plants was as good as that from the crossed.

Blind florets in rye are apparently due to different causes. While failure of pollen tube growth and con-

sequent failure of fertilization is in part responsible, embryo sacs fail to develop in a small percentage of them. Still others abort at an early stage after the formation of the embryo sac. Both Krasniuk (1935) and Peterson (1934) report that highly self fertilized lines give the least loss of seed setting under field conditions.

An examination of pollen from fifteen plants gave an average of 62 per cent good grains with a range from 1 to 90 per cent. Since rye plants with 14, 15, or 16 chromosomes may be present (Hasegawa, 1934), it was thought that this might be responsible in part for the various abnormalities present in the embryo sacs and pollen grains. However, an examination of the chromosome condition in nine plants showed insufficient irregularity to account for this, though two of the nine had 8 chromosome pairs present.

#### SUMMARY

Rye plants are partially self sterile, seeds developing on less than 10 per cent of the selfed florets.

Embryo sacs of ovaries collected at several dates after self pollination were examined, as were those of cross pollinated ovaries. In a considerable proportion of cases fertilization occurred following selfing so that much of the self sterility cannot be attributed to failure of pollen tube growth but must be due to events subsequent to penetration of the embryo sac by the tube. Failure of pollen tube growth plays some part, because a larger number of ovules were fertilized after cross than after self pollination.

A large proportion of self pollinated ovaries abort in early stages. In these cases no cellular endospermal tissue is formed. This accounts for much of the self sterility. There is also abortion in some crossed ovaries but far less than in selfed ones.

In a proportion of ovules which develop, there are irregularities in the endosperm. These irregularities are more numerous in selfed than in crossed ovules.

In from 5 to 10 per cent of the ovules on most plants examined no embryo sac had formed. The cause of this has not been determined but is probably the same as the cause of the considerable percentage of aborted pollen in most plants.

# THE COMPARATIVE HISTOLOGY OF SOME OF THE LAMINARIALES 1

Arlo I. Smith

SINCE MUCH of the previous work on the histology of this group of brown algae has led to considerable contradiction and confusion, this paper is an attempt to present the results of a comparative study of several members of the Laminariales. In its genesis this problem was also meant to deal with the developmental nature of the plant tissues, but upon the promise of its assuming gigantic proportions it has been limited almost entirely to the adult tissues as they exist, without considering how the elements making up those tissues became what they are. Chief among the contradictory questions in existence are those relative to the so-called sieve tubes. What are the sieve tubes in the Laminariales and how do they differ from those of the Spermatophytes?

So far as the author has been able to find there are in existence no photomicrographs of the detailed structure of any of the Laminariales; however, Sykes (1908) did present six photomicrographs of Macrocystis pyrifera and Laminaria saccharina stipes in cross section taken at very low magnifications.

"Trumpet hyphae," or filaments made up of elongate cells with fluted ends (fig. 16), were first discovered in Laminaria saccharina and Alaria esculenta by Reinke (1876) and described as "lange Parenchymzellen mit aufgeblasenen Enden." Wille (1885) later more accurately described and figured them. Will (1884) figured and described trumpet hyphae in Macrocystis and Nereocystis. In his work on obliteration of sieve tubes in Laminarieae, Oliver (1887) reports sieve tubes in Laminaria, Alaria, Agarum, Thallassiophyllum, Ecklonia, Lessonia, Macrocystis, and Nereocystis. In addition to the trumpet hyphae, the last two genera have certain thick-walled perforated cells which he terms "true sieve tubes" resembling sieve tubes of Cucurbita of the squash family.

Humphrey (1887), in working on Agarum Turneri, corroborates Oliver's report of trumpet hyphae in that genus. Rosenthal (1890) traced the development of young sieve tubes in Macrocystis and Thallassiophyllum. Results reported a year later by

<sup>1</sup> Received for publication April 12, 1939. Presented at the annual meeting of the Botanical Society of America in Richmond, Virginia, December 29, 1938.

The author wishes to acknowledge indebtedness to Dr. T. C. Frye and Dr. George B. Rigg for their counsel and criticism during the progress of the research, and to the Oceanography Department of the University of Washington for use of its collecting facilities.

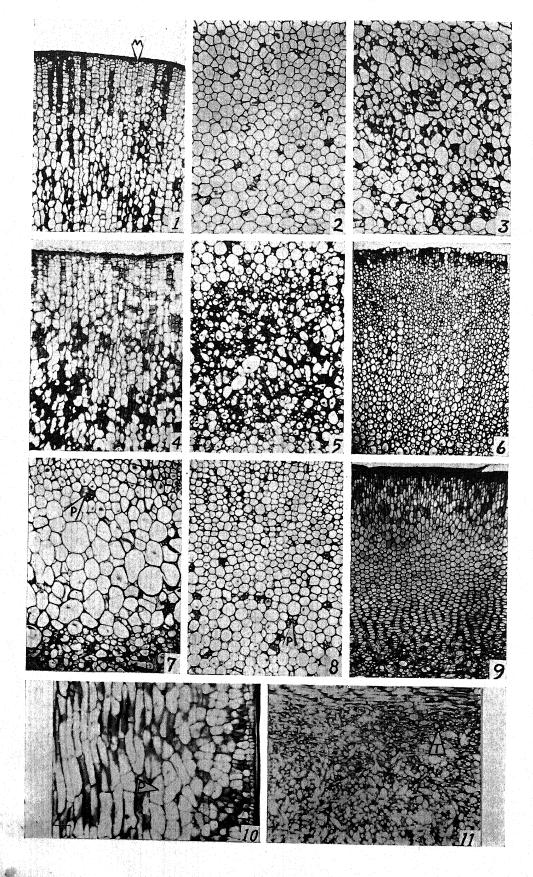

Setchell (1891) on Sacchoriza (Laminaria) dermatodea compare favorably with Rosenthal's (1890) conclusions on sieve tube development in Macrocystis. Trumpet hyphae are poorly developed in Laminaria bulbosa according to Barber (1889). Wille (1897) considers the trumpet hyphae to be homologous with the large sieve tubes reported for Macrocystis, while Oliver (1887) maintains that they are of different nature. It seems fairly agreed that the large tubes in the medulla of Macrocystis and Nereocystis are true sieve tubes (Oltmanns, 1904; Oliver, 1887; Rosenthal, 1890; Sykes, 1908; Will, 1884; Wille, 1897), but the question is whether or not the trumpet hyphae should be called sieve tubes. Oltmanns (1904) also questions the use of the term trumpet hyphae. The author does not like the use of the term trumpet hyphae and, instead, in the remainder of the paper proposes to call them trumpet filaments. The term filament seems to be desired rather than hyphae because the former seems to be more nearly related to algae than the term hyphae. Kibbe (1915) reports trumpet filaments, which she also terms sieve tubes, present in Alaria fistulosa.

MATERIALS AND METHODS.—Algae examined for this problem include Laminaria saccharina (L.) Lamouroux, Cymathere triplicata (Post. and Rupr.) J. Agardh, and Costaria costata (Turn.) Saunders of the Laminariaceae, Nereocystis Luetkeana (Mert.) Post. and Rupr. of the Lessoniaceae, and Pterygophora californica Rupr., and Alaria tenuifolia Setchell of the Alariaceae. Classification follows Setchell and Gardner.

The plants examined were of various ages and sizes and were collected both in spring and fall in Puget Sound and the Straits of Juan de Fuca and were preserved directly, either in 7 percent formalin in sea water, or in strong chromoacetic acid in 50 per cent sea water. Fresh material was used only as a check on preserved material.

Sections were made both by the freezing sliding microtome and by the paraffin method. Material to be sectioned in paraffin was previously dehydrated and infiltrated by the butyl alcohol method. Both longitudinal and transverse sections were made from the blade, the transition region between the blade and stipe, the stipe, and from the hapteres. Sections were cut 15 to 20 microns thick on the sliding microtome and I to 10 microns on the rotary microtome.

Microchemical tests were made largely upon sections preserved in formalin or fixed in strong chromoacetic acid solution and run up into 70 per cent alco-

hol (50 per cent ethyl and 20 per cent n-butyl) to which was added a small quantity of glycerine. Microchemical tests included use of iodine-potassium iodide, chlorozine iodide, concentrated sulphuric acid, concentrated chromic acid, concentrated calcium chloride, cuprammonia, and corralin soda.

Sections were stained in methylene blue, aniline blue, corralin soda, fast green, gentian violet, eosin, or safranin. The safranin proved the best general stain, and the pit membranes were more plainly visible in this than in the other stains tried.

Sections were studied under magnifications up to 1800 diameters, with the aid of a  $20\times$  ocular and oil immersion objective.

EXTERNAL MORPHOLOGY.—In the Laminariales the entire plant or frond is usually divided into three distinct regions—viz., a flattened blade or blades, a cylindrical or more or less flattened stipe either simple, dichotomous or irregularly branched, and a holdfast varying from solid discoid to clusters of simple or branched hapteres.

In Laminaria saccharina is found a stipe of variable length but usually around 10 to 20 centimeters. The stipe is cylindric below and flattens above into the transition of blade and stipe. The blade is membranaceous to coriaceous and has an undulate margin. The numerous hapteres are dichotomously branched.

Cymathere triplicata has a small discoid holdfast rather than one of hapteres. The stipe is short, stout and solid, cylindric below and flattened above into the transition region. The linear undivided blade is thick and leathery at its base, becoming thinner at

All photomicrographs were made with a Leitz "Makam" Mikro-Aufsatzkamera, taken on Commercial Ortho Nitrate film. No retouching has been done. Unless otherwise stated, the figures were stained in safranin and the photomicrographs made without the use of filters.

the tip. Three diagnostic longitudinal folds extend the length of the blade.

A typical specimen of Costaria costata has a 5-costate blade which tapers quite rapidly into the flat transition region. The stipe is usually short but may be quite variable in length. Hapteres are dichotomously branched and usually form an extensive hold-fast.

In Pterygophora californica is found a stipe which is comparatively large and has concentric growth rings when viewed in cross section. The stipe is terete below but flattens above in the transition region. From along the margins of this transition region sporophylls arise, there often being 10 to 20 on the plant. A terminal blade is also present, continuing from the transition region, and is frequently hardly larger than the sporophylls.

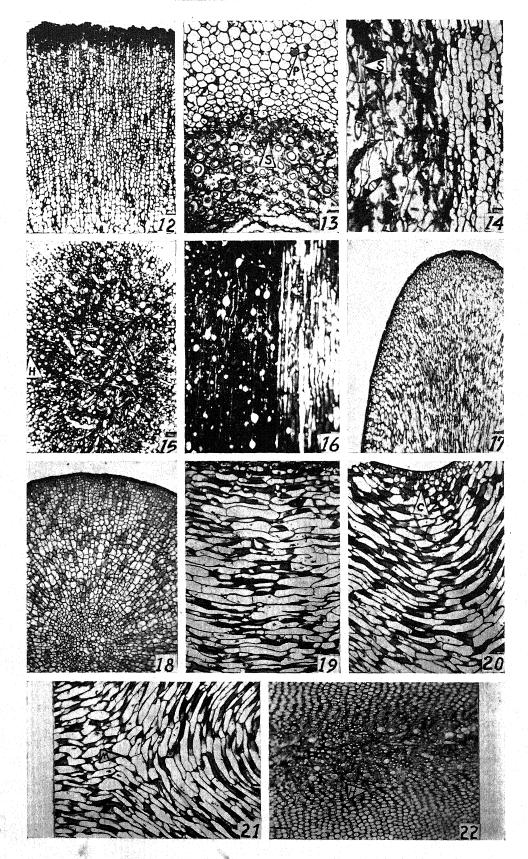

Alaria tenuifolia has a comparatively short stipe which is solid and unbranched and at its upper end flattens into the transition region, whence continues a distinct percurrent midrib through the blade. Sporophylls may be present along the upper part of the stipe. The holdfast is not large and is made up of slender dichotomously branched hapteres.

Nereocystis Luetheana has a very long stipe which is bulbous at its upper end and from which several blades arise in either two or four sets. The transition region is in the pneumatocyst and bases of the blades. The stipe is hollow throughout most of its length, being solid near its base. Hapteres branch dichotomously to form a massive interwoven holdfast.

In the following comparisons the stipe is treated first because its structures make for better orientation.

THE STIPE.—In all cases, whether or not the stipe is solid, there are three definite regions to be observed in both cross and longitudinal sections. The outer cells for several layers deep are definitely of

PLATE I.—Fig. 1-11.—Fig. 1. Costaria costata, cross section of outer cortex of the stipe showing radial rows of cells and the epidermal meristem (M). Compare with figure 4. Section 8 microns thick. ×55.—Fig. 2. C. costata, cross section of inner cortex of the stipe showing cessation of radial arrangement of cells. A few end walls are present in which pits (P) are arranged in a circle. The medulla is located on the lower side of the figure. Compare with figure 42 of plate IV. Section 8 microns thick. ×55.—Fig. 3. C. costata, cross section of medulla of the stipe showing presence of isodiametric cells of varying sizes. Section 8 microns thick. ×55.—Fig. 4. C. costata, longitudinal section of outer cortex of the stipe showing radial arrangement of cells and the epidermal meristem. Compare with figure 1. Section 8 microns thick. ×55.—Fig. 5. Alaria tenuifolia, cross section of the medulla of the stipe showing varying sizes of the isodiametric cells. A few of the smallest cells are trumpet filaments. Compare with figures 8 and 12. Section 10 microns thick. ×55.—Fig. 6. Cymathere triplicata, cross section of the outer cortex of the stipe showing radial rows of cells. Section 8 microns thick. ×55.—Fig. 7. C. triplicata, cross section of the inner cortex of the stipe where radial arrangement of cells is indistinguishable. At P appears an end wall in which the pits are scattered indiscriminately. At the bottom is the edge of the medullary region. Compare with figure 48 of plate IV. Section 8 microns thick. ×125.—Fig. 8. Alaria tenuifolia, cross section of the inner cortex of the stipe in which radial arrangement of cells has become negligible. Pits in the end wall may be seen at P in their characteristic circular arrangement. Compare with figures 5 and 12; the former would fit below figure 8, the latter above. Also compare with figure 45 of plate IV. Section 10 microns thick. ×55.—Fig. 9. Laminaria saccharina, cross section of the cortex of the stipe. The cells are in radial rows, and filaments from the medulla at the bottom extend in the intercellular spaces of the inner cortex. Some of the trumpeted filaments run otherwise than axially and may be seen in the medulla. Compare with figures 10 and 11 and with figures 44, 47, and 50 of plate IV. Section 7 microns thick. ×55.—Fig. 10. L. saccharina, longitudinal section of the outer cortex of the stipe showing the epidermal meristem and pits (P) in tangential and end walls. Compare with figure 9 and with figures 44, 47, and 50 of plate IV. Section 5 microns thick. ×125.—Fig. 11. L. saccharina, longitudinal section of the medulla of the stipe showing abundance of trumpeted filaments (T) and other filaments running in all directions. Inner cortex is at upper side of the figure. Compare with figure 9. Section 5 microns thick. ×55.

a meristematic nature. This has been called an epidermal meristem (fig. 1, 4, 10), but it must be understood that this meristem is a region of several lavers of cells and not a single epidermal layer. The meristem commonly gives rise to radial rows of cells which may or may not appear radial in longitudinal section (fig. 10) but which when viewed in cross section (fig. 1, 6, 12) nearly always have cells, at least those of the outer cortical region, in radial rows. Epidermal meristem in all plants studied is composed of between five and ten lavers of cells, the outermost always being covered with a mucilage like coating. Diatoms are very frequently found imbedded in the coating on almost any part of the plant. The cells of the meristem are much smaller than those of the cortex and are isodiametric or somewhat shorter radially (fig. 1, 4, 6, 10, 12), Plastids are found in abundance in the surface layers and in some instances almost completely occupy the entire meristematic region. Activity of the meristem in all cases gives rise to a radially arranged cortex whose cells become successively larger in closer proximity to the medulla. The typical example may be cited in figures 5, 8, and 12, which are from Alaria.

Pits are present in the walls of all cells throughout the plant, but it is in the cortex (fig. 2, 7, 8, 42) that they become the most conspicuous. The epidermal meristem is not excepted in having pits, though they are often comparatively small and few in number. Because of the abundance of plastids, the pits are often masked unless the sections are exceedingly thin. Further detailed description of pits follows in the description of the cortex.

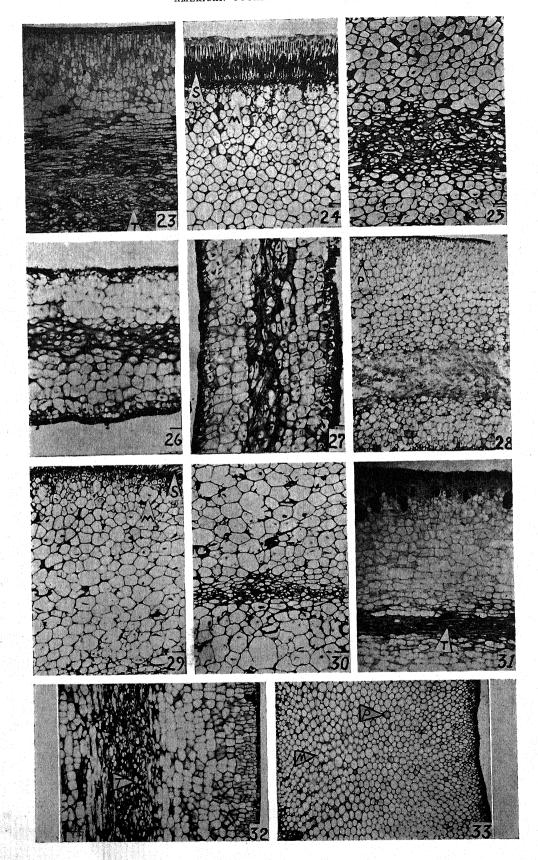

The cortical region (fig. 8) is to be understood as that region from the epidermal meristem inward, to a medulla (fig. 3, 5, 11) whose cells are usually of a smaller diameter and more elongate and where many branched filaments are frequently abundant. The cells of the cortex are approximately isodiametric and become only slightly longer as they near the medulla. The shape of the medulla may be elliptic in cross section as in Costaria, Alaria, Pterygophora, and Laminaria, or it may be circular as in Nereocystis and Cymathere. The shape of the medulla in cross section near a flattened transition region is nearly always elliptic, flattened in the plane of the flattening of the blade.

A distinction is often made between the inner and outer cortex, in which case the former refers to those cortical cells surrounding the medullary region, the cells of which may or may not be in radial rows. Sykes (1908) refers to those inner cortical cells in which radial arrangement is not perceptible as primary tissue and to those radial rows of cells added by the epidermal meristem as secondary tissue and termed outer cortex. This is apparently not infallible, because in some forms the radial arrangement goes into the medulla; especially is this so in Pterygophora, and in those forms with an elliptic medulla, the cortical cells adjacent to the ends of the ellipse are still in radial rows. However, since this paper does not take into consideration the development of tissues, no further discussion will be given here as to the feasibility of using the terms primary and secondary tissues. Outer cortex throughout this paper refers to those cells of the cortex from just within the epidermal meristem to a point halfway to the medulla.

The terms epidermal meristem, cortex, and medulla are the same as those used by previous workers.

All cells of the stipe have pits in their transverse walls, as is the case throughout the plant, and it is perhaps here that they are more commonly known

PLATE II.—Fig. 12-23.—Fig. 12. Alaria tenuifolia, cross section of the outer cortex of the stipe showing radial row arrangement. Compare with figures 5 and 8 of plate I. Section 10 microns thick. ×55.—Fig. 13. Nereocystis Luetkeana, cross section of the inner cortex and a portion of the medulla of the stipe in which appear a pitted end wall (P) of the cortex and a sieve plate (S) in one of the many sieve tubes of the medulla. The space between the cells of the medulla is filled with mucilaginous material. Compare with figures 36 and 39 of plate IV. Section 8 microns thick. ×55.—Fig. 14. N. Luetkeana, longitudinal section of the inner cortex and the outer medulla of the stipe showing typical sieve tubes at S and fragments of small interwoven filaments. Compare with figure 13 and figures 36 and 39 of plate IV. Section 5 microns thick. ×55.—Fig. 15. Pterygophora californica, cross section of medulla of the stipe showing typical arrangement of filaments, nearly all of which are trumpeted. Compare with figure 16. Note the somewhat gradual transition from cortex to medulla. Section 10 microns thick. ×46.—Fig. 16. P. californica, longitudinal section of juncture of medulla and cortex of the stipe showing the medulla composed almost entirely of trumpet filaments. Note the transition from cortex to medulla. Compare with figure 15. Section 15-20 microns thick. ×55.—Fig. 17. Costaria costata, longitudinal section of tip of a haptere showing the epidermal meristem and elongated cells of the medulla. Section 5 microns thick. ×55.—Fig. 18. Nereocystis Luetkeana, cross section of a haptere showing epidermal meristem and typical cell arrangement. Compare with figure 17. Stained with fast green and a red filter used. Section 10 microns thick. ×230.—Fig. 19. Laminaria saccharina, longitudinal section of medulla (at bottom) and cortex (at top) of the haptere showing elongated cells of the former and epidermal meristem of the latter. Section 10 microns thick. ×55.-Fig. 20. L. saccharina, longitudinal section of cortex in the crotch (C indicates direction of branching) of a dichotomously branching haptere showing the epidermal meristem and elongated cortical cells. Compare with figures 19 and 21. Section 10 microns thick. ×55.—Fig. 21. L. saccharina, longitudinal section of branching medulla in the haptere just behind location of figure 20 showing the nature of the branching medulla at M. The dichotomous haptere branches are off to the upper and lower right sides of the picture. Compare with figures 19 and 20. Section 10 microns thick. ×55.—Fig. 22. L. saccharina, cross section of the medulla of the transition region of the stipe and blade showing typical arrangement of filaments. Filaments may be seen extending into intercellular spaces of the inner cortex as at H. Compare with figure 23 of plate III. Section 5 microns thick.

than elsewhere. With the exception of Cymathere, the pits in the end wall are arranged in a circle around the edge (fig. 42, 45, 47). In Cymathere triplicata (fig. 7, 48) the pits are arranged in an indiscriminate fashion over the end wall. No explanation has been found for the difference or similarity of the pattern of pit distribution. The pits in the tangential and radial walls of the cells seem to follow no definite pattern of arrangement, but in many instances the circular arrangement is frequently found. Pits are relatively abundant in the tangential walls (fig. 10, 51) but are almost lacking in radial walls. This perhaps indicates that radial conduction is of nearly as much importance as longitudinal conduction and that tangential conduction is not carried on to any great extent through pits in the radial walls. Pits may vary in size from 1 micron to nearly the diameter of the whole cell, but the majority of them are 3 to 5 microns in diameter. Smallest pits are found in Alaria. The pits have a thin membrane across them in all cases. The membrane stains only slightly in safranin, and no stain was found in which excellent preparations for detailed study could be made. Bits of protoplasm are easily seen clinging to the membrane (fig. 42), and in some cases where there is a crack in the wall the stained pit membrane can be detected readily. Sykes (1908) reports sieve fields in the pits of Laminaria and Macrocustis, but the author is unable to see holes in the pit membrane even under magnification of 1800 diameters, nor does there seem to be any indication that such is the case in any forms studied, even including Laminaria saccharina on which Sykes reported. Since the pits themselves are even so small in diameter as to be only one micron at times, any holes through the membrane must be extremely small.

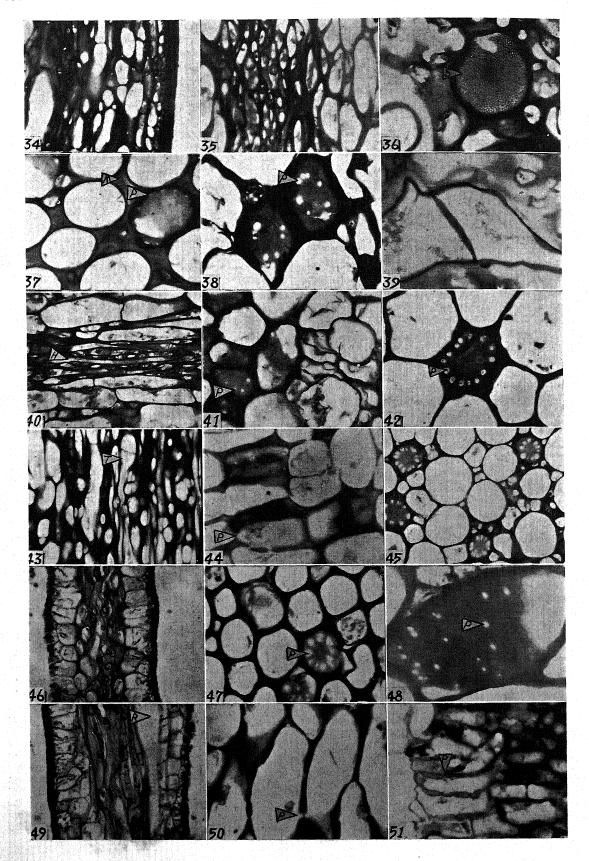

The number of pits in an end wall is not definite (fig. 45), and in all the plants observed may vary from a few to as many as 20.

Other than the increase in length and often lack of definite radial arrangement of cells, the only difference between the structure of the outer and inner cortex appears to be in the less compactness of cells nearer the medulla. When cells are not compact, all the forms studied have small diameter filamentous cells present in their mucilaginous intercellular spaces (fig. 7, 9, 45). This condition is common near the medulla. In some cases (Alaria and Costaria) the cells of the medulla are not elongate, and of course in these the inner cortical cells remain short and nearly isodiametrical.

The cortex of Pterygophora is unique among the forms studied in having concentric rings of tissue which have been called annual growth rings (Frye, 1918). The cells in the rings which would correspond to the summer wood of woody Spermatophytes are slightly smaller and appear to be much more densely filled with protoplasm than the other cortical cells. Pits present throughout the cells of the stipe are of the type found in the other forms (fig. 51). Other than the presence of the seasonal growth rings in the cortex there is no essential difference between the histology of the stipe of Pterygophora and the other plants discussed herein.

The medulla is different in the various forms studied. The medulla of *Nereocystis* is hollow in the center for most of its length through the stipe, and the cellular portion is rather narrow in comparison to the thickness of the other tissues. The other plants have a solid medulla but with the filamentous cells of varying compactness. Within the inner cortex of *Nereocystis* are axial filaments composed of cells of the same diameter as the inner cortical cells (fig.

PLATE III .- Fig. 23-33 .- Fig. 23. Laminaria saccharina, longitudinal section of medulla and cortex of the transition region of the stipe and blade showing numerous trumpet filaments of the medulla (T) and the gradation into short cells of the cortex. The epidermal meristem appears dark. Compare with figure 22. Section 4 microns thick. ×55.-Fig. 24. Cymathere triplicata, cross section of the outer cortex of the transition region of the stipe and blade showing outer region bearing a layer of sporangia (S). M represents mucilage ducts just beneath epidermis. Note that the isodiametric cells of the cortex are not in distinctly radial rows. Section 8 microns thick. ×55.—Fig. 25. C. triplicata, cross section of the medulla of the transition region of stipe and blade. Note cells of inner cortex and trumpet filaments in the medulla. Section 8 microns thick. ×55.—Fig. 26. Costaria costata, cross section of non-costate portion of the blade showing middle layer of trumpet filaments. The outer layers of cells are of the same thickness and are isodiametric. No mucilage ducts are present. Compare with figure 27. Section 8 microns thick. ×125.—Fig. 27. C. costata, longitudinal section of non-costate portion of blade. See below figure 26 for description. Section 8 microns thick. X125.—Fig. 28. C. costata, cross section of a costate portion of the blade showing middle layer of slightly trumpeted filaments, the outer layer on the ridged side of the blade (top) about twice as thick as that of the fold side, and a pitted end wall appearing at P. Section 8 microns thick. ×55.—Fig. 29. Cymathere triplicata, cross section of outer layer of the blade. Sporangia are present at S, and a mucilage duct may be seen at M. The cells are isodiametric, and outer layers on both sides of the medulla (compare with figure 30) are of the same thickness. Section 8 microns thick. ×55.—Fig. 30. C. triplicata, cross section of middle layer of the blade in which are present slightly trumpeted filaments. Compare with figure 40 of plate IV. On either side of the middle layer are isodiametric cells of the two outer layers. Section 8 microns thick. ×230.—Fig. 31. Pterygophora californica, longitudinal section of the middle and an outer layer of the blade. Trumpet filaments (T) are present throughout the medulla. Section 10 microns thick. ×55.—Fig. 32. Laminaria saccharina, longitudinal section of part of the blade showing middle layer composed of trumpet hyphae (T) and an outer layer of nearly isodiametric cells. Compare with figure 43 of plate IV. Section 10 microns thick. ×55.—Fig. 33. Alaria tenuifolia, cross section from the medulla to the surface of the midrib of the blade showing pits in the outer layer, especially at P and large intercellular spaces near middle layer filled with mucilage M. Extremely small cells to the left are those of the middle layer. Compare with figures 34 and 37 of plate IV. Section 7.5 microns thick. ×55.

14) but three to five times longer. These filaments are not compact, and among them are interspersed small, branching, non-trumpeted filaments which run in all directions. Intercellular material is mucilaginous and absorbs the stain readily. The cross walls of the large medullary filaments are true sieve plates (fig. 13, 36), and hence the term sieve tube has been used in discussing them (Oltmanns, 1904; Oliver, 1887; Rosenthal, 1890; Sykes, 1908; Will, 1884; and Wille, 1897). Sieve tubes in the medulla are only slightly trumpeted (fig. 14), and the protoplasm within is nucleate. Long filamentous cells with prominent fluted ends such as are present in Pterygophora (fig. 16) are not frequently seen in the stipe of Nereocystis. Branches are occasionally found in the sieve tubes, and when present merely run parallel with the main sieve tube. No connections were seen between the sieve tubes and the small muchbranched non-trumpeted filaments among them. The many branched filaments of the medulla are connected with cells of the inner cortex, and their transverse walls have pits in a circular pattern similar to the cells in the cortex.

The medulla of *Costaria* (fig. 3) is made up of nearly isodiametric cells of various sizes, no trumpeted filaments of any sort being present. Pits in the typical circular pattern are present in all the end

walls throughout the medulla just as in every other part of the stipe. Mucilaginous material is not abundant, the stipe is fairly solid, and intercellular space is minimized. The small cells intermingling with the large ones are not filamentous as in *Nereocystis*, and it is the presence of these small cells which forms a demarcation between the inner cortex and medulla (fig. 3). The inner cortical cells are all nearly the same size (fig. 2, 3). Nothing even remotely resembling a sieve tube or sieve plate is present in the stipe of *Costaria*.

The stipe of Alaria has a medulla (fig. 5) quite similar to that of Costaria except that the cells are more elongate and intertwining. There is also a trumpeting of the cells, though not so pronounced as in Pterygophora (fig. 16). All the cells of the medulla have their end walls with the typical circular arrangement of pits just as in the rest of the plant, and there is nothing present which might be called a sieve plate.

A cross section of the stipe of Laminaria presents a view of the medulla that very closely resembles that of Alaria (fig. 5). In longitudinal view the medulla of Laminaria is much more abundant with elongated filaments which are very prominently dilated at their cross walls (fig. 11). At the outer portion of the solid medulla are found trumpeted fila-

PLATE IV.—Fig. 34-51.—Fig. 34. Alaria tenuifolia, cross section of a portion of the blade near the midrib showing the middle layer and one of the outer layers. The middle layer is very thin and is composed of a few trumpeted filaments. Section 7.5 microns thick. ×192.—Fig. 35. Pterygophora californica, cross section of the middle layer of the blade showing the trumpeted filaments in cross section. Compare with figure 31 of plate III. Section 8 microns thick. ×400.—Fig. 36. Nereocystis Luetkeana, cross section of medulla of stipe to show a sieve plate. The white area in the sieve plate is a portion of the plate that was cut away in sectioning. Compare with figure 39 and with figures 13 and 14 of plate II. Section 8 microns thick. ×440.—Fig. 37. Alaria tenuifolia, cross section from the midrib of the blade. Cells from vicinity of M in figure 33 of plate III to show thickness of cell walls, the intercellular space filled with mucilage (M), and pits (P) in the end wall. The large white area in the end wall is where part of that wall was cut away in sectioning; the pits are fairly small. Section 7.5 microns thick. ×400.—Fig. 38. Pterygophora californica, cross section of outer layer of the blade showing the typical circular arrangement of pits (P) in the end walls. Section 8 microns thick. ×400.—Fig. 39. Nereocystis Luetkeana, longitudinal section from the medulla of the stipe showing a sieve tube in which the sieve plate, sectioned at 3 microns, is turned obliquely, presenting a view of both its thickness and surface. Compare with figure 36 and with figure 14 of plate II. Section 3 microns thick. ×440.—Fig. 40. Cymathere triplicata, longitudinal section of the middle layer of the blade to show trumpeted filaments at H. Note the thinness of the middle layer and compare with figure 30 of plate III. Section 10 microns thick. ×192.—Fig. 41. Laminaria saccharina, cross section of outer layer of cells in the blade showing pits (P) in their end walls. The large white space in the end wall of the indicated cell is a part that was cut away in sectioning. Section 8 microns thick. ×400.—Fig. 42. Costaria costata, cross section of cortex of stipe showing typical circular arrangement of pits in the end wall. At P may be seen bits of protoplasm clinging to the membrane across the pit. Compare with figure 2 of plate I. Section 8 microns thick. ×400.—Fig. 43. Laminaria saccharina, longitudinal section of middle layer of blade showing trumpeted filaments (T). Compare with figure 32 of plate III. Section 10 microns thick. ×192.—Fig. 44. L. saccharina, longitudinal section of the outer layer of the blade sectioned I micron thick to show the membrane across pits (P) in cell walls. Compare with figures 41, 47, and 50. ×400.—Fig. 45. X192.—Fig. 47. Laminaria saccharina, cross section of cortex of stipe to show pits in their typical circular arrangement in the end walls. Compare with figure 50. Section 7 microns thick. ×95.—Fig. 48. Cymathere triplicata, cross section from the cortex of the stipe showing the end of one of the cells in which the pits (P) are scattered indiscriminately over the wall. The white area on the right side of the picture is where part of the wall was cut away in sectioning. Compare with figure 7 of plate I. Section 8 microns thick. ×400.—Fig. 49. Nereocystis Luetkeana, longitudinal section of the blade showing the middle layer of slightly trumpeted filaments and the thin outer layers. R represents a space where the outer layer separated somewhat from the middle layer in slide preparation. Section 8 microns thick. ×192.—Fig. 50. Laminaria saccharina, longitudinal section of cortex of the stipe showing pits (P) in tangential walls. Compare with figure 47. Section 5 microns thick. ×400.—Fig. 51. Pterygophora californica, longitudinal section of cortex of stipe showing pits (P) in tangential walls. Compare with pits in end walls of the blade in figure 38. Section 15-20 microns thick. ×192.

ments running a much straighter axial course than in the inner medulla and which gradate into the elongate non-trumpeted cells of the inner cortex. Although the trumpeted filaments in the outer medulla do branch at their cross walls, it is in the inner medulla that the filaments branch more profusely. These branches in some cases extend all the way across the medulla and into the intercellular spaces of the inner cortex (fig. 9). All the filaments of the medulla have pits in their cross walls or else these pits have become a single membrane (a single pit) stretching across the whole cell. The latter condition appears to happen frequently, but it is in Laminaria that it is found to occur more than in any other plant examined. Note in figures 47 and 45 how the pits are so close together that a single thin membrane would not be a great step removed from the condition existing there. Sykes (1908) explained this as a step in the formation of sieve plates, but as far as the investigator has been able to discern there are no holes such as are present in the sieve plate of Nereocystis; he is content to think of the membranes as pit membranes. Other than this membrane, Laminaria does not show evidence of having sieve tubes, especially in the sense that Nereocystis and Macrocystis (Sykes, 1908; Will, 1884) have.

A glance at the medulla of Cymathere shows it to be terete and set off from the inner cortex rather abruptly (fig. 7) by the decrease in cell size. Filamentous cells are much intertwined in the medulla, and though their sizes vary considerably, none of them are conspicuously trumpeted. Pits in the end walls of the cells are scattered in an indiscriminate pattern just as throughout the other cells of the plant (fig. 7, 48). Nothing even remotely suggesting a sieve plate or sieve tube is to be seen in the stipe of

Pterygophora has many long, very prominently trumpeted filaments and many short, muchbranched, non-trumpeted ones forming the much entangled mass of medulla (fig. 15, 16). There is a gradual transition between the cells of the inner cortex and those of the medulla. This transition is marked by the diminishing length and flutedness of the inner cortical cells. The trumpeted filaments have cross walls with the typical circular arrangement of pits just as throughout the stipe. No semblance of sieve tubes is noted.

In the much-branched non-trumpeted filaments forming entanglements in the medulla of all forms studied the end walls are pitted, and the remaining cylindric walls have no pits except at branching cells. These pits are in the typical circular arrangement in all except Cymathere, which of course has the indiscriminate distribution of pits throughout.

THE HAPTERE.—All of the species examined except Cymathere, have a holdfast composed of branching hapteres. Cymathere has a discoid holdfast. The hapteres arise from the base of the stipe and are usually rather closely intertwined. The epidermal meristem is nearly always thinner than that of the stipe and is almost imperceptible in Costaria and Laminaria (fig. 20). In Pterygophora the epidermal meristem is nearly as thick as in the stipe and in the older hapteres gives rise to concentric growth rings just as in the stipe. The haptere of Nereocystis (fig. 18) shows a fairly well defined epidermal meristem, usually much thicker than in the other species except Pterygophora.

The tip of a haptere has no special meristematic region other than the epidermal meristem which is not different than elsewhere (fig. 17). In the crotch of a branching haptere (fig. 20) there is also the same epidermal meristem. Nothing resembling a single apical cell is present in the haptere. The epidermal meristem, just as in the stipe, usually gives rise to radial rows of cortical cells. Pterygophora hapteres may have concentric growth rings present just as in the stipe, depending of course upon their age. Cells of the cortex in every case are long nearer the center of the haptere and are also usually larger

in diameter (figs. 17, 18, 19, 20).

There is no medulla of intertwining filaments resembling that of the stipe present in any of the hapteres. In longitudinal section there is no structural difference between the cortex and the very center of the haptere, other than the slightly longer cells in the center. In cross section the cortex always has radial rows of cells, the rows going all the way to the center in Nereocystis and very near the center in Pterygophora. When radial arrangement is not present, the center of the haptere resembles the inner cortex of the stipe in structure. In the center at a branch, as in Laminaria (fig. 21) the cells are seen to be running in two directions from the main axis without any difference in appearance of the cells in-

Pits in the end walls of all of the cells in the hapteres are in the typical circular arrangement and are scattered indiscriminately over the other walls. Pits are more numerous on the tangential than on the radial walls.

The base of the stipe has a medulla which is almost without semblance to that of the main part of the stipe. In this region the transition into hapteres is gradual, and in stipes with a medulla of elongate filamentous cells, the transition cells into the hapteres are merely elongate and closely resemble inner cortical cells. Where a haptere arises fairly high on the stipe, as is often the case, should there be a well defined medulla, there is no branching of that medulla into the haptere. The haptere arises at the outer surface of the cortex, and the cortical cells protrude into it. In the transition of stipe into hapteres in Nereocystis the sieve tubes gradate into merely elongate cells, and the medulla is not different from the cortex in structure. Nothing resembling sieve plates or sieve tubes is present in the hapteres of any of the plants examined.

In Cymathere, the representative with the discoid holdfast, the base of the stipe spreads out and is composed of isodiametrical cells all of nearly the same size. Differentiation into medulla and cortex is hardly distinguishable, but the epidermal meristem is still evident. The pits are present in all the walls and are not arranged in a circle as in the other algae examined but are scattered indiscriminately over the walls, as throughout the whole plant (fig. 48).

The transition region.—The tissues of the transition region between the stipe and blade are described in the same terms as used for the stipe—that is, epidermal meristem, outer cortex, inner cortex, and medulla. The meristematic transition region adds cells to the blade and stipe. Because of the many differences of the transition regions and blades of the species examined these will be treated separately rather than together as was done for the stipe and hapteres.

A cross section of the transition region of Laminaria is broadly elliptic in shape and flattened in the plane of flattening of the blade. The epidermal meristem and cortex of the transition region are hardly different from the stipe proper. No mucilage ducts are present here or in the stipe or hapteres. Other than the differences in shape of the tissues, comparisons of figures 9 and 10 of the stipe with figures 22 and 23 of the transition region show no important structural changes. Trumpet filaments are abundantly present throughout the medulla (fig. 23). Pits in the transition region are no different from those described in the stipe and hapteres, being abundant on the transverse and tangential walls but sparsely scattered over the radial walls. Filaments run radially into the cortex from the medulla (fig. 22) as in the stipe, but somewhat more prominently.

A broad thick transition region is characteristic of Cymathere, which also has a thick coriaceous blade. Mucilage ducts, not present in the stipe, make their appearance in the outer cortex of the transition region (fig. 24), and sporangia may or may not be present at the surface. The epidermal meristem does not give rise to distinct radial rows of cells (fig. 24) as is the case in the stipe (fig. 6). Cells throughout the cortex are nearly isodiametric (fig. 24), becoming only slightly elongate as they near the medulla. The medulla is relatively thin and very flatly elliptic in cross section. Its elements are made up of much entangled filaments many of which are trumpeted (fig. 25). In this plant the figures shown resemble the blade more closely than the stipe. Pits are still in the scattered rather than circular arrangement and differ in no manner from those of the stipe and hapteres. The pits on the transverse and tangential walls are more numerous than on the radial walls.

The transition region of Costaria is not essentially different in structure from that described for the stipe. Comparisons show that the medulla is relatively larger and less compact in the transition region and that the cells are less variable in size, somewhat elongate, and slightly trumpeted. The cortex is not very thick, and its radial arrangement is still discernible, indicating that an epidermal meristem is still functioning. Pits in the transition region are not different from those of the stipe and hapteres.

Alaria has a transition region in which the epidermal meristem is evident and which forms an outer cortex of cells in radial rows. No mucilage ducts are present, nor are they found elsewhere in the plant. A comparison of the transition region with the stipe yields few differences. The stipe is terete with an elliptic medulla, while the transition is elliptic in its entirety. The medulla of the transition region is less compact than that of the stipe. While the medulla of the stipe is made up of large and small cells, most of which are isodiametric, the medulla of the transition region is composed almost entirely of elongate trumpeted filaments. Many of these filaments extend into the intercellular spaces of the inner cortex as in Laminaria (fig. 9) and ultimately connect with cortical cells. Perhaps this abundance of trumpeted filaments in the transition region is partially accounted for by the fact that Alaria bears sporophylls here, as does Pterygophora.

Pterygophora has a broad flattened transition region bearing sporophylls and in cross section is similar to Alaria. The epidermal meristem forms radially arranged cortical cells, and evidence of production of concentric growth rings similar to those of the stipe may be found in the cortex. No mucilage ducts or cells are found, nor were they present in the stipe or hapteres. The structure of the medulla is not different in the transition region from that in the stipe, and figure 25 might well represent a section from the former rather than the latter. In the medulla, the trumpet filaments are abundant and the ends of the cells are prominently fluted.

The transition region of Nereocystis in the pneumatocyst of the stipe, and the bases of the leaf blades show mucilage ducts abundant in the outer cortex. Such mucilage ducts are not present in the stipe and hapteres. The outer cortex cells are in radial rows while those of the inner cortex are not definitely so. Typical pitted cells are present throughout the cortex as in the stipe, and the medulla is composed of sieve tubes with true sieve plates. Small, many-branched non-trumpeted filaments are also present in the medulla, just as in the stipe, but more compact in the former. No essential difference in structure is found between the stipe and the transition region.

The blade.—A section through a blade of all species examined shows three layers of tissues—a middle layer, corresponding to the medulla of the stipe, and a layer on either side of the middle layer corresponding to the cortex of the stipe (fig. 26, 27). The outermost cells appear to be nothing more than an epidermis, not resembling a meristem such as is found in the stipe. In the discussion of sections of the blade in this paper, the tissues will be referred to as middle layer and outer layers rather than as medulla and cortex.

The blade of Costaria has costae extending from the transition region to the tip. These costae are ridges on one side of the blade and folds on the other. On each side of the blade there is alternately a ridge, then a fold, etc. A cross section through a costa shows an outer layer twice as thick on the ridge side of the middle layer as on the fold side (fig. 28). By comparing a cross section (fig. 28) and a longitudinal section of the costa, the cells in the outer layers are seen to be almost isodiametrical, being only slightly elongate near the middle layer. The middle layer is made up of a loose mass of much-branched mostly non-trumpeted filaments; some of the filaments running axially are definitely trumpeted and frequently branched. Mucilaginous material occupies the intercellular spaces throughout the blade, being fairly abundant in the middle layer. There are no mucilage ducts present in the blade, nor any place else in the plant. The small non-trumpeted filaments frequently connect the two outer layers almost directly across the middle laver. The transverse walls of the middle and outer layers all have the characteristic circle of pits (fig. 28) as elsewhere in the plant. Pits are much more abundant in the transverse walls than in the other walls, being sparsely and indiscriminately scattered in the latter and not in the typical circular arrangement.

The inter-costal areas of the blade of Costaria resemble the costal portions just described except that both of the outer layers are of the same thickness (fig. 26, 27) and the cells of these outer layers are not elongated to any extent. The middle layer is made up of both trumpeted and non-trumpeted filaments, the latter being the more numerous. This layer in the inter-costal area of the blade is somewhat thinner and more compact than that of the costal area

Cymathere has a blade that is usually rather thick and coriaceous especially near its base. The blade has mucilage ducts (fig. 29) present in the outer layers which connect with those of the transition region. It will be remembered that the stipe has no mucilage ducts. The middle layer of cells is comparatively thin (fig. 30, 40) and is composed of much elongated trumpet filaments (fig. 40). In the outer layers the cells gradate (fig. 40) into the trumpet filaments of the middle laver. Pits in the transverse walls throughout the blade are abundant and of the type peculiar to Cymathere—that is, they are scattered and not arranged in a circle. A small number of scattered pits is present in the other walls. In figure 29 sporangia (S) are present at the surface of the blade, being just like those in the transition region (fig. 24).

A cross section of the blade of Pterygophora (fig. 35) is almost identical to that of Cymathere and needs no further explanation, but in longitudinal view (fig. 31) the blade shows the presence of mucilage cells rather than ducts in the outer layers. In Pterygophora (fig. 31) a rapid transition from the nearly isodiametric cells of the outer layer into the elongate trumpet filaments of the middle layer is seen. This is more marked than in Cymathere. Pits are abundant, comparatively large, and circularly arranged in the transverse walls (fig. 38) and sparsely and indiscriminately scattered in the other walls.

The blade of Laminaria contains mucilage ducts in the outer layer of isodiametric cells, the latter becoming longer as they near the middle layer (fig. 32). The middle layer is composed of much-branched filaments running in all directions, and many of those running longitudinally are trumpeted (fig. 32, T). Pits in the transverse walls are abundant, arranged in a circle, and are of the type found throughout the plant (fig. 41, 44).

In Alaria a percurrent midrib extending through the median axis of the blade is several times thicker than the expanded part of the blade. A cross section of an outer layer of the midrib (fig. 33) shows the cells much smaller toward the outside and much larger nearer the medulla. The intercellular spaces are fairly large and filled with mucilaginous material. Examination of longitudinal sections of the midrib proves that the cells of the outer layer are not isodiametric except at the epidermal layer, while the remaining cells are elongate to as much as five times their diameter near the middle laver. The transition is gradual until the middle layer is reached, where there are then present many muchbranched, trumpet filaments of small diameter. The expanded portion of the blade is very similar to that of Costaria (fig. 26, 34). The middle layer is comparatively wide, mucilaginous, and filled with trumpeted filaments, while the cells in the outer layers are somewhat elongate. Pits are much more abundant in the transverse walls than in the remaining walls and are in the typical circular arrangement (fig. 33, 37). Figures 33 and 37 show the thickness of the cell walls and mucilaginous material filling intercellular

Nereocystis has blades that are comparatively thin and in which the outer layers are only 2 to 5 cells thick (fig. 46, 49). The middle layer is also thin and is composed of branching filaments made up of slightly elongate, mostly non-trumpeted cells (fig. 49). Mucilaginous material is abundant in the middle layer. Cell walls with sieve plates (fig. 36) are not present in the blade as in the stipe. The typical pitted walls in which the pits are arranged in a circle are present, both in the middle and outer layers.

MICROCHEMICAL TESTS.—In testing for cellulose materials in the plants examined, it was found in every case that the cell walls were soluble (as is cellulose) in concentrated sulphuric acid and in concentrated chromic acid. The walls in Pterygophora were dissolved with difficulty. Cuprammonia acted upon the cells very slowly, and the tests yielded negative results for cellulose, the walls being insoluble. With iodine-potassium iodide following sulphuric acid, cellulose gives a blue color, but the test on cell walls yielded only a faint blue at its best and certainly not sufficient to indicate pure cellulose. The cell walls remained more yellowish-brown than blue. With chloro-zinc iodide solution the cell walls remained yellowish-brown which, were they cellulose, should become a violet color.

In only one species, Costaria costata, did the iodine-potassium iodide test yield a blue color on in-

tercellular material. The color was definitely blue black, indicating the probable presence of some type of hemicellulose (Tunmann, 1913). This material did not turn violet in chloro-zinc iodide, nor blue in iodine-potassium iodide when previously treated with sulphuric acid. It was not colored by corralin soda but was colored by safranin, aniline blue, and methylene blue.

Corralin soda gave evidence of varying amounts of callose in all species, depending largely upon the age of the cells. When callose is found, it is nearly always in either trumpet filaments or sieve tubes or both. Costaria gave only slight indication of callose formation even in the older plants. Tests with chlorozinc iodide gave a brick red color, also indicating callose (Tunmann, 1913). The same material stained a brown color in iodine-potassium iodide. Sieve plates of Nereocystis turned brownish in iodine-potassium iodide, brick red in chloro-zinc iodide, slightly bluish in iodine-potassium iodide following sulphuric acid, and in corralin soda gave a red color in varying quantities and shades.

Discussion.—The statement made by Humphrey (1887) that the lamina or blade of Agarum Turneri is both anatomically and morphologically a terminal expansion of the stipe also holds true for the species discussed herein. This may be even more emphasized for these species since trumpeted filaments are present in the blade as well as in the stipe. They were not reported in the blade of Agarum. If it is assumed that the trumpet filaments are for conduction and, in the case of Costaria, the trumpet filaments are more abundant in the transition region and the blade than in the stipe, then it seems very logical that the blade is morphologically only a flattened stipe.

Comparative study of the hapteres, stipes, transition regions, and blades shows that they are all of the same type of cells, except perhaps the true sieve tubes of Nereocystis, but developing under different internal environmental conditions. As cortical cells are added by the epidermal meristem, the more central cells are not able to keep pace with them by cell division and are stretched into elongate cells. Stretching also gives rise to what Setchell (1891) terms pulled out pore canals to form connecting filaments. This is in agreement with Will (1884) and Rosenthal (1890). The cells of the medulla of Costaria stipes are not elongate because the stipe itself does not become very long even in the adult plant. This is in direct contrast to the case in Nereocystis. Similar pits are present throughout all cells of the plants studied, even including the epidermal cells. The pits in the transverse walls are in circular arrangement (fig. 47, 42, 45) and are scattered indiscriminately over the radial and tangential walls. There are two exceptions. Nereocystis has true sieve plates with many holes in them (fig. 36) present in the medulla, all the other cells being typical. The other exception to pits in circular arrangement is found in Cymathere in which they are scattered indiscriminately (fig. 48) over the transverse walls just as in the radial and tangential walls but in greater abundance. There appears to be no particular significance in the arrangement of pits except that they are more often similar than dissimilar in arrangement. Sieve tubes reported by Kibbe (1915) in Alaria fistulosa are not present in Alaria tenuifolia.

Again referring to the effect of internal environment upon cells, examination of sections of hapteres and of the outer cortex of the stipe shows that those tissues under compression and slower in elongating (fig. 21) do not have trumpeted cells or pulled out pore canals as is the case in the medulla of the stipe and the middle layer of the blade. Histologically then, the plants studied are true thalli, and there is no essential difference in the parts that make up the plants.

Pits are present in the cells of the epidermal meristem as well as in those of the medulla. There is a difference in size of pits, those in the younger outer cells being smaller and fewer than in the inner cells. The pits average 2 to 15 microns in diameter, being nearer the former figure in nearly all cases. Sykes (1908) suggests that in the formation of sieve tubes the pits converge to form a single membrane which then becomes perforated forming a sieve plate. In Laminaria saccharina, upon which Sykes worked, the author did find the pits larger than in the other species studied (fig. 47), and this was the only case of possibly convergent pits, but even here he found no holes through the membrane of the pits even under magnifications of 1800 diameters with sections cut only one micron thick.

It seems logical that only those filaments or cells having walls with holes in them should be called sieve tubes. Only such walls are found (in those plants studied) in *Nereocystis*, and here the term sieve tube does not appear to be a misnomer. These sieve tubes have nucleate cytoplasm, and there are no companion cells such as in Spermatophytes. The definition of a sieve tube does not have to exclude nuclei or include companion cells.

The walls of trumpeted filaments present in the stipe, transition region, and blade are pitted rather than perforated just as are cells throughout the plant, whether or not they are trumpeted. It seems no more logical, merely because they are elongate and trumpeted, to call these filaments true sieve tubes than to call the unelongated pitted cells of the cortex sieve tubes. They are of the same type but have developed under different internal environmental conditions. Pitted cells are common in various tissues of all types of Spermatophytes, but we do not call them sieve tubes. When Oliver (1887) worked on the obliteration of sieve tubes in Nereocystis and Macrocystis by callose, he found that not only did the true sieve tubes form callose but also the trumpeted filaments. He concluded that these sieve tubes and trumpeted filaments are not homologous. The method of callose formation is not known for certain, and there is no proof that the material must pass through holes in the cell wall. Perhaps it might be formed within the cell where it is found. Thus it seems that callose is not necessarily limited to true sieve tubes

Rosenthal (1890) suggests that lateral protuberances may arise on the walls of inner cortical cells, thus giving rise to small interwoven cells in the medulla. Such protuberances are often found in the species studied and are suggestive of what Rosenthal proposed, but the author did not trace the development of filaments penetrating the medulla from the cortex, or vice versa, whichever the case might be.

Setchell (1891) suggested that the pulling out of pore canals laterally, when cells separate in growth, may give rise to connecting filaments in Sacchoriza (Laminaria). This might be the case in any or all forms treated herein, and one can easily imagine how lateral connections can arise by division of the cell in the canal. Regardless of the method of development, the abundant, intertwining, non-trumpeted filaments of the medulla are different from true sieve tubes especially in that their cross walls have pits, not holes. This is apparently in contradiction to Sykes' (1908) findings but not to those of Oliver (1887). No pits are found in the medullary filaments other than on the cross walls, because the cells are usually connected only at their ends. The same is true of the trumpeted filaments which run a nearly straight axial course in most instances.

Thick walled inner cortical cells of the stipe as reported in Agarum Turneri (Humphrey, 1887), Macrocystis luxurians (Will, 1884), Laminaria saccharina, Laminaria digitata, and Alaria esculenta (Reinke, 1876), and Nereocystis Luetkeana (Oliver, 1887) are not present in the species the author has examined. Sykes (1908) states that the mucilage present in intercellular spaces, as in Alaria (fig. 37), is really much swollen wall material. Figure 37 shows the definite thickness of cell walls, be they primary or secondary, separated by mucilaginous material, called swollen wall material by Sykes (1908). The intercellular material commonly has small filaments running through it, especially in the inner cortex (fig. 9, 22, 37, 45), indicating that it is not penetrated with difficulty. Naturally when stretching takes place in the inner tissues as a result of growth toward the outside, more space is produced within. Since the cells may secrete mucilage, perhaps the intercellular material is secreted from the cells after the primary wall or middle lamella has been destroved. If this be the case, then the walls are not thick, but if the mucilaginous intercellular material is swollen walls, in many cases the cell walls are thick, especially where the cells are not compact. This intercellular material gives no tests definitely indicating that it is either cellulose or callose, but it is readily colored in many stains including methylene blue, aniline blue, and safranin. In the case of Costaria, the mucilaginous material stained dark blue with iodine-potassium iodide, perhaps indicating the presence of some type of hemicellulose (Tunmann, 1913). The wall proper, be it primary or secondary, gives various reactions to microchemical tests. Some indicate that it is of cellulose and some that there is no cellulose present. As the walls are unchanged in color with various iodine reagents, fungous cellulose or a similar cellulose derivative is suggested. Ruthenium red has been known to stain walls of Nereocystis (Karrer, 1916; Rigg, 1925), indicating that pectose is present, but the author made no tests with this stain. It appears that walls of the Laminariales are of a modified form of cellulose not commonly met with in higher plants. Karrer (1916) reports algin, a pectose-like material, present with cellulose in the cell wall. It is generally believed that the walls are of a pectose-like material accompanied by cellulose.

Callose deposits may appear in trumpeted filaments and sieve tubes in varying proportions, apparently depending largely upon the age of the cells involved. Results obtained from Laminariales studied by other workers and microchemical tests on the species included here seem to be conclusive that callose is a special carbohydrate material distinct from cellulose and pectose.

Oliver (1887) and Sykes (1908), in their work on obliteration of sieve tubes in Laminaria, Macrocystis, and Nereocystis, present excellent figures of callose formations. Such formations are also found in all the plants examined here, but in Costaria it is almost negligible. No completely obliterated trumpet filaments were found in Costaria.

Mucilage ducts may or may not be present in tissues of the stipe or blade; none are present in hapteres. They are of no particular importance in connection with this paper, and their presence is merely noted. However, attention may be called to the fact that special mucilage cells rather than ducts are present in the outer layers of the blades of *Pterygophora* (fig. 31).

### SUMMARY

The comparative histology of Costaria costata, Laminaria saccharina, Cymathere triplicata, Nereocystis Luetkeana, Alaria tenuifolia, and Pterygophora californica is presented upon the basis of their stipes, hapteres, transition regions, and blades, in that order. The stipe, haptere, transition region, and blade are all of essentially the same type of cells except developed under different environmental conditions. The plant as a whole is nothing more than a thallus. The term "trumpet filament" is proposed to replace the term "trumpet hypha." Trumpeted filaments are not true sieve tubes, since their end walls are made up of pits rather than of a perforated membrane or plate. True sieve tubes have perforated sieve plates, nucleated cytoplasm, and no companion cells. True sieve tubes are reported only for Nereocystis among those species here examined. Pitted cells are present throughout the entire plant in all species considered. Pits are in a single circle in the transverse walls of all except Cymathere, in which case the pits are scattered indiscriminately over all the walls. In addition to pits in circular arrangement, Nereocystis has true sieve plates as end walls. Callose may be formed generally throughout the medullary cells but not in other cells of the plant. Cell wall material appears to be of modified cellulose of uncertain character.

## NUCLEAR STRUCTURE AND BEHAVIOR IN SPECIES OF THE UREDINALES 1

### D. B. O. Savile

Anyone who studies the illustrations accompanying the many papers dealing with the cytology of the rust fungi must be impressed by two features common to all of them. The first of these is the remarkable variation, both in size and in appearance, of the rust nucleus in different organs and in different parts of the life-cycle. Very little comment is to be found concerning this variability. The second surprising feature is the remarkable dearth of convincing division figures elsewhere than in the basidium. In most stages no figures except a few telophases are to be found, and the interpretation of some of these is questionable.

It seemed to the writer that an elucidation of the nuclear structure and behavior throughout the lifecycle might greatly help our understanding of the general biology of the rusts and also clarify the imperfectly understood diploidization process. An attempt has accordingly been made to interpret nuclear behavior in the group as a whole, employing a number of species for study, rather than to elucidate what might prove to be the peculiarities of a single species.

A start was made on the investigation under the direction of Prof. J. G. Coulson, in the Department of Plant Pathology, Macdonald College, McGill University, during the winter of 1935-1936, at which time the writer held a Macdonald Alumni Scholarship. The bulk of the work was done at the Univer-

<sup>1</sup> Received for publication April 21, 1939. Papers from the Department of Botany of the University of Michigan, No. 693.

sity of Michigan, under the direction of Prof. E. B. Mains, during the winters of 1937-1938 and 1938-1939; during this period the writer held the Emma J. Cole Fellowship in Botany. The writer takes this opportunity to express his sincere gratitude for the support that has made the investigation possible.

The writer is deeply grateful to Prof. H. J. Brodie, of the University of Manitoba and formerly of Macdonald College, and to Prof. B. M. Davis and Prof. W. R. Taylor, of the University of Michigan, for their valuable interest and advice throughout the work. Thanks are also due to the many others who have given advice at various times.

HISTORICAL SURVEY. — Cytological investigation of the rusts extends back to the work of Schmitz (1880), who discovered conjugate nuclei in the mycelium and urediniospores of Coleosporium Campanulae. The first extensive and important work in this field, however, did not appear until Sappin-Trouffy (1896) described and illustrated nuclear division in a number of species. This paper is of great importance because it indicated the fusion of the paired nuclei and the subsequent reduction division in the teliospore.

The progress in this field of investigation may be divided into three periods. In the first, started by Sappin-Trouffy, the nuclear fusion in the teliospore was stressed, and the origin of the dikaryon was overlooked. Sappin-Trouffy's work was followed by similar studies by Juel (1898) and Holden and

Harper (1903).

The second period started when Blackman (1904) described the initiation of the dikaryon at the base of the aecial primordium of Phragmidium violaceum by the migration of the nucleus of one cell into an adjacent one through a narrow pore. Shortly after this announcement Christman (1905) reported a slightly different method of diploidization in Phragmidium speciosum; namely, the fusion of two adjacent cells into a single large binucleate cell that gave rise to the aeciospore chain. These findings stimulated great interest in rust cytology, and during the next twenty years the aecial stages of some forty species were examined by Olive (1908), Kursanov (1910, 1922), Fromme (1914), and Lindfors (1924), to name the most important investigators. Nuclear migration was reported in a few species, equal-cell fusion in the majority, and both methods were seen in a number of species distributed through several genera. There was considerable disagreement concerning the relative significance of the two methods. Christman, Fromme, Kursanov (1910), and Olive all considered the few cases of nuclear migration seen by them to be pathological; but Blackman (1904), Blackman and Fraser (1906), Welsford (1915), and Kursanov (1922) all described nuclear migration through a small pore unaccompanied by equal-cell fusion. Opinion also differed during this period concerning the nature of the sexual process and its bearing on the phylogeny of the Uredinales. All the theories advanced were founded upon the assumption that the pycniospores were function-

The discovery by Craigie (1927a, 1927b) that the pycniospores of Puccinia Helianthi and P. graminis are indeed functional ushered in the third period of rust cytology and immediately diverted the attention of uredinologists into new channels. He showed that aecia were produced when the pycnial nectar of different pustules was mixed and spores thereby transferred; but that when this was not done and insects, which serve to transfer the spores in nature, were excluded, the pustules remained sterile. Papers by Craigie (1928, 1933), Hanna (1929), Allen (1930, 1931, 1932, 1933a, 1933c, 1934a, 1934b), Brown (1932, 1935), and Lamb (1935) clearly indicate that we may expect most of those rusts the pycnia of which are well developed to prove heterothallic. Ashworth's (1931) study of Puccinia Malvacearum gives weight to the belief that those forms with pycnia rudimentary or absent are homothallic.

Since the function of the pycniospores became known, various attempts have been made to demonstrate the mechanism whereby the pycniospore nuclei are transferred to the cells that they are to diploidize in the aecial primordium. Hanna (1929) suggested that the pycniospores of Puccinia graminis send germ-tubes down through the ostiole of the pycnium to which they have been transferred and form an independent mycelium the cells of which fuse with those of the aecial primordium. Allen (1934a) maintained the same to be true for Melampsora Lini.

Craigie (1933) demonstrated the fusion of pycniospores of *Puccinia Helianthi* with flexuous hyphae that emerge from the ostioles of the pycnia. These hyphae are distinguished from the stiff, tapering paraphyses by being blunt, flexuous, and very variable in length and abundance. Recently Buller (1938) has described the same process for *Puccinia graminis*.

Andrus (1931) saw what he termed trichogyne tips emerging from the stomata of bean leaves infected by *Uromyces appendiculatus* but presented no conclusive evidence that the pycniospores fused with them or that they led directly to the aecial primordium. Rice (1933) reported similar hyphae in the stomata of *Oxalis* leaves infected by *Puccinia Sorghi* and considered them to be trichogynes.

Lamb (1935), working with Puccinia Phragmitis, reported the fusion of pycniospores with ostiolar hyphae but could not distinguish the two distinct types described by Craigie. His illustrations, however, do show that some of the hyphae were fairly blunt at the tips, and it is possible that the flexuous hyphae were not well developed. He considered the passage of pycniospore nuclei from the ostiolar hyphae to the primordia, through the existing mycelium, to be the only method of diploidization by the pycniospores; but he noted that the coalescence of pustules of opposite strains also brought about the production of aeciospores. The latter method was demonstrated by Brown (1935) for P. Helianthi after he had already (1932) shown that diploidization could be effected in this way by a diploid pus-

Allen, working with Puccinia triticina (1931) and P. coronata (1932), described hyphae that push out not only through the stomata but between the epidermal cells close to the pycnia. She believed that the pycniospores fused with these hyphae and diploidized the small clusters of cells immediately beneath them. From these clusters the sporophyte was thought to spread to the aecial primordium both by the growth of these diploid hyphae and by the division and migration of nuclei through the existing mycelium.

Lamb's paper provides such an exhaustive discussion of the problem of sexuality in the rust fungi that to deal fully with the subject here could serve no useful purpose. He regarded the evidence for the presence of female sex organs to be very unconvincing and concluded that it was safest to avoid the use of the terms "male" and "female" and to regard the pycniospores as having a syngamic rather than a sexual function; that is to say, they are to be considered comparable to the oidia of the Hymenomycetes, the function of which was demonstrated by Brodie (1931, 1936). His viewpoint is thus in contrast with that of Andrus and Rice, each of whom regarded the rusts as having both true spermogonia and trichogynes. Andrus also spoke of the basal cells in the aecium as egg cells.

MATERIALS AND METHODS.—The following rusts have been included in the study: Uromyces Fabae

(Pers.) de Bary, U. Lespedezae-procumbentis (Schw.) Curt., U. Hyperici (Spreng.) Curt., Puccinia Sorghi Schw., P. Malvacearum Bert., P. Hieracii (Schum.) Mart., Melampsora Bigelowii Thüm., and Tranzschelia fusca (Pers.) Diet.

Uromyces Fabae, U. Lespedezae-procumbentis, and Puccinia Sorghi supplied most of the material for the aecial stage: the first from field collections and the others from greenhouse cultures with controlled mixing of the pycnial nectar. The teliospore germination stages were studied mainly from Puccinia Malvacearum, Melampsora Bigelowii, and Uromyces Lespedezae-procumbentis.

A wide variety of fixing and staining methods was tried, but the bulk of the material was handled by a few methods found suitable for the purpose.

In the descriptions of the figures the staining and fixing methods are given, in abbreviated form, except where no cytological detail is recorded. The abbreviations used are those given below.

The most generally used fixing solution was formalin-acetic-alcohol (F. A. A.: formaldehyde [40 per cent], 7 cc.; glacial acetic acid, 7 cc.; 50 per cent alcohol, 100 cc.). Somewhat different proportions were occasionally used, but this proved most generally useful, particularly where prompt embedding was not possible.

Chrom-acetic solution (Chr. Ac.: chromic anhydride, 0.5 g.; glacial acetic acid, 3 cc.; water, 100 cc.) was found useful with Heidenhain's haematoxylin for demonstrating certain details.

Duggar's (1909) modification of Gilson's fluid (D. G.) was used extensively because it is very suitable for material stained by the Feulgen method.

Two other solutions were used to a lesser extent—namely, acetic-alcohol (A. A.: glacial acetic acid, 20 cc.; 95 per cent alcohol, 80 cc.) and formalin-acetic-dioxan (F. A. D.: formaldehyde [40 per cent], 7 cc.; glacial acetic acid, 7 cc.; 50 per cent dioxan, 100 cc.).

While the appearance of the fixed nuclear structures was essentially similar after all fixations, the staining reactions of the differently fixed material varied greatly with certain staining methods.

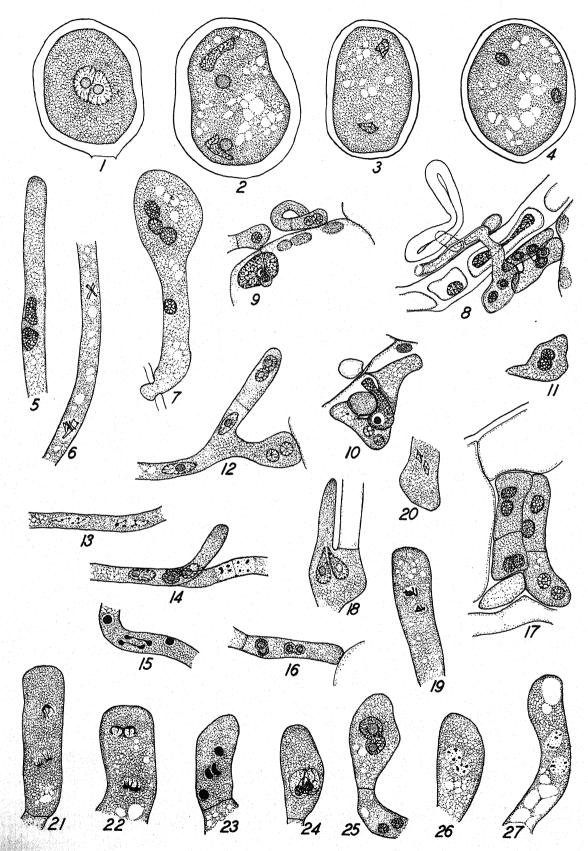

It was soon realized that the usual methods alone would not allow the complete solution of the problem, and an attempt was made to find methods that would supplement or replace them. While no one method was found to be universally applicable, two were discovered that, in conjunction with the generally used Heidenhain's haematoxylin schedule, cleared up most of the difficulties.

The first of these was based on the method described by Naylor (1926), but different dyes and a different buffer series were used. The buffer used was McIlvaine's disodium-phosphate citric-acid series, cited by Clark (1922). Sections of material fixed in F. A. A. were transferred from water to 0.5 per cent aqueous erythrosin for twenty minutes, dipped in water, and stained for twenty minutes in aqueous methylene blue. After a brief rinsing in water, they were transferred to a buffer solution di-

luted 1:50 from stock, at about pH 4.5, and left for about three hours. The buffer solution was changed twice during this period. Finally the slides were quickly rinsed in distilled water, dehydrated rapidly to avoid undue loss of dye, and mounted in xylol-balsam. Since the staining results are not markedly different over a range from about pH 4.0 to 5.0, elaborate precautions need not be taken in preparing the solutions. The stock solutions are most easily kept free from molds by covering them with a film of toluene. As might be expected, the reticulum of the host nucleus stains blue in contrast to red nucleoli and chloroplasts and red or purple cytoplasm. The rust nucleus, however, in most stages stains a bright red in strong contrast to the deep blue cytoplasm. As will be shown later, this surprising reaction seems to be due to the staining of ergastic material, perhaps mainly simple proteins, rather than the chromatin in the nuclei of the parasite. The writer has not had the opportunity to test the buffered methylene-blue eosinate method of Lillie and Pasternack (1936), which only recently came to his notice, but it would probably give results somewhat similar to this method. Several samples of each dye were used without apparent difference in the results. This method will be referred to as buffer staining, abbreviated in the description of figures to "buffer."

The second important method, new to rust investigations as far as the writer is aware, is the application of the Feulgen stain. The staining solution was prepared according to the formulae of both Margolena (1932) and de Tomasi (1936), but it was not possible to distinguish between the results. A single sample of basic fuchsin, unfortunately of unknown origin, was used throughout. The solutions kept perfectly. This method is not to be regarded as universally applicable, but it is extremely useful in studying the pycnial stage, in determining the precise distribution of chromatin within the nucleus, and in elucidating the nuclear divisions in the aecium. As the aeciospores, urediniospores, and teliospores approach maturity, some substance giving a red tinge to the cytoplasm is often present; the color is not identical with that of the chromatin, being a true red rather than purple, but it is close enough to it to hinder observation, particularly when the chromatin is finely dispersed. The method, therefore, is often disappointing for these stages, though good preparations are sometimes obtained. All fixing fluids except the chrom-acetic proved satisfactory with this method. It proved uniformly disappointing with all rusts and all host plants examined. Even with a long hydrolysis, which tends to loosen the sections from the slide, it was never possible to get more than a dull nuclear stain. The staining schedule used was that given by de Tomasi, fast green F. C. F. being used as a counterstain. This counterstain is to be understood in all cases, though the method will be referred to simply as Feulgen staining.

When the disposition of the chromatin is discussed, it is to be understood that by "chromatin" is meant the material, presumably nucleoprotein, that

reacts to the Feulgen stain. At the same time it is not to be inferred that nothing but nucleoprotein is involved in the movement; but in such minute nuclei it is in general only the chromatin that can be distinguished from the karyolymph.

Heidenhain's haematoxylin, usually with orange G as a counterstain, proved useful in the teliospore and basidium, particularly where it was desired to show spindle structure, and was used in other stages as a check on newer methods as well as to provide a comparison with the figures of earlier investigators. Its failure to render chromatin distinguishable from certain other materials, and the difficulty found in getting proper differentiation at certain stages owing to the accumulation of deeply stained ergastic material, are against its exclusive use: it should be used mainly when other methods fail.

Another point that should be more generally remembered is that the apparent size of minute structures stained by this method may be far greater than the true size. This is particularly true when chromic fixing fluids have been used. It is possible by this method to make the delicate spindle fibers distinctly visible, although in reality they are probably below the limit of vision. The method is similar to the mordanting and precipitation techniques used in demonstrating bacterial flagella. Other structures are similarly affected, and a stain heavy enough to demonstrate the spindle often causes the chromosomes to appear as a single clump rather than as individuals. No other haematoxylin technique having been used,

the method will be referred to simply as haematoxy-lin staining.

Other methods occasionally used have been the following: Safranin counterstained with fast green in clove oil; various modifications of Flemming's triple stain; aqueous methylene blue counterstained with erythrosin in clove oil; and Gram crystal violet counterstained with orange G. The Gram formula used was the rapid method of Dr. Guilford B. Reed, as given by Racicot, Savile, and Conners (1938). Its main use was in delimiting the inner nuclear sphere in certain stages.

The optimum thickness for paraffin sections in such a study as this was found to be 7  $\mu$ . Sections much thinner show few complete figures, and in sections appreciably thicker there is too much interference with the resolution of fine details, particularly if the more opaque dyes have been used.

The germination of aeciospores and urediniospores was studied mainly by germinating the spores upon thin agar films on slides. After appropriate intervals the preparations were fixed and were then handled like paraffin sections. Teliospore germination was studied in part by the use of sections and in part by scraping the germinating spores, or the basidia only in the case of *Melampsora*, into a drop of water upon a slide. After teasing the spores apart, a drop of fixing fluid was applied and allowed to dry, and the slide was then handled in the normal way. This apparently crude treatment sometimes yields remarkable results; even if half the basidia are lost, ample material remains if the germination was good.

All examination of cytological detail was made with a Zeiss ×90 apochromatic objective of 1.3 N. A. and compensating eyepieces and with the condenser at about N. A.=1.2. The majority of the drawings were made with the  $\times 15$  eveniece and with the camera lucida adjusted to give a magnification of 2600 diameters on the drawing board; these are reproduced at a magnification of 1920 diameters. The few drawings reproduced at other magnifications have the scale indicated in the descriptions of the figures.

In the preparation of the figures it has sometimes been necessary to use slightly conventional methods, and these should be understood before the illustrations are studied. In the first place the limitations of monochrome rendering of details distinguished in the slide largely by color differences are quite serious. To make nuclear structures stand out from the surrounding cytoplasm, they have often been drawn somewhat more boldly than they appeared in the slide; but important dimensions, such as the diameters of the prophase chromosomes, have been reproduced as accurately as possible. In the second place, certain apparently amorphous structures, which cannot be reproduced naturally in a line drawing, have been indicated by a geometrical type of stippling to distinguish them from the reticulately stippled cytoplasm. Examples of this may be seen in figures 30, 31 and 34, and the method has also been used in a number of other drawings. Wall sculpturings have been left out in all drawings of spores since they are sometimes hard to distinguish without special methods, and they have no bearing on the present problem. For the sake of uniformity and to avoid further explanations, drawings have been oriented as though the host leaf were horizontal, and it has been assumed that all aecia opened on the lower surface and all other sori on the upper.

RESULTS.—The rust nucleus is commonly described and illustrated as having a relatively large nucleolus inside a reticulum that is very variable in both size and stainability. Sometimes the whole outer zone is represented as perfectly hyaline. At other times the entire nucleus is indicated as much smaller, being about the size of the so-called nucleolus, and it then contains either no visible nucleolus or only a very small granule the identity of which is hard to determine.

This variability puzzled the writer until a number of buffer-stained preparations were obtained in which a deeply-stained granule was visible in virtually every one of these inner spheres, or so-called nucleoli, of the larger, expanded type of nucleus (fig. 105). This granule could often be seen to be surrounded by an optically empty zone similar to the "heller Hof" commonly seen about the nucleolus in fixed nuclei of the higher plants. This at once suggested that the small granule, rather than the sphere in which it lay, was the nucleolus.

Attempts were made to secure adequate differentiation with haematoxylin to see how this inner sphere of the nucleus behaved during mitosis and the

subsequent nuclear reconstitution. Although by this means it was often possible to distinguish the granule within the inner sphere (fig. 103), it was seldom possible to discern the details of division owing to the presence, in dividing cells, of some substance with a great affinity for the haematoxylin. If destaining was carried far enough to clear all the cytoplasm. the nuclei were also almost completely destained. This was particularly true of the aecia, but it applied also to all other stages except the basidium, in which the nuclei are not of the expanded type.

It was not until the Feulgen method was used in an attempt to determine the precise distribution of the chromatin in the different types of nuclei that their real behavior began to be understood. Most of the features of the nuclear cycle have now been worked out, and in order to make them clear it is proposed to trace the entire life-cycle of the typical heterothallic, long-cycled rust, starting with the ure-

The morphology of the several fruiting structures has been described in detail for a number of genera by Moss (1926, 1929), Kursanov (1922), and Fromme (1914), among others, and will be taken up in the present paper only as it affects the problem at hand.

The uredinium.—The mature urediniospore has what will be termed the fully expanded type of nuclei (fig. 1)—that is to say, all the chromatin lies in the outer sphere, while the inner sphere is usually homogeneous in appearance and is a clear glassy green when the Feulgen stain is employed. It will soon be seen that these inner and outer spheres of the nucleus cannot be homologized with any parts of the nucleus of the higher plants and that they require distinctive names. It is proposed, therefore, to call them, respectively, the endosphere and ectosphere. These terms, while sufficiently descriptive to be useful, have the advantage of not implying any function that might later prove to be lacking.

Germination of the urediniospore is accompanied or preceded by a reversion of the nuclei to the unexpanded state—that is to say, they decrease in size and lack the endosphere, presenting instead the appearance of a small but typical nucleus. The change in form has been followed for Uromyces Fabae. The endosphere moves to one side until it lies against the ectosphere membrane. This membrane then breaks down locally and reforms behind the endosphere, which is accordingly left in a cupulate depression outside the nucleus. From here it drifts off into the cytoplasm (fig. 2) and eventually disintegrates. The greatly distorted nuclei now contract (fig. 3) and eventually round up into the typical unexpanded form (fig. 4). A minor disadvantage of the Feulgen method as here employed is that it is not possible to distinguish the true nucleolus of the unexpanded nucleus, everything but the chromatin being uniformly stained by the fast green. A recent paper by Semmens and Bhaduri (1939) describes a modification whereby the counterstain is removed from everything but the nucleolus; though satisfactory for chromosome studies in the higher plants, such a method would not meet the requirements of a problem of this kind. So far there has been no opportunity to perfect a differential stain for this purpose.

As germination proceeds, the nuclei move out into the germ-tube, either retaining the unexpanded form or becoming slightly expanded, with some of the chromatin outside what is then to be regarded as a new endosphere; but in either case the appearance with the Feulgen stain is unaltered, except that they may become somewhat distorted (fig. 5). If the host is not immediately penetrated the nuclei undergo simultaneous division in the germ-tube. The prophase of such a division is seen in figure 6. It will be noticed that the dividing nuclei are far apart, and this seems to be generally true. It is improbable that the nuclei ever divide side by side in the tube. Where two nuclei having a dumbbell shape are seen abreast in a narrow hypha or germ-tube, it is probable that they represent two daughter nuclei slipping past one another to restore the pairing of compatible strains after division; this device takes the place of the clamp-connection. After the division, unexpanded nuclei are again formed, as shown in figure 7; here, incidentally, a secondary spore is in process of formation, as often occurs when germination takes place under unfavorable conditions.

Figure 8 shows the invasion of a pea leaf by the germ-tube of a urediniospore of *Uromyces Fabae*. The empty, collapsed spore can be seen on the leaf surface. It will be seen that several lobes were thrown out by the germ-tube before one reached and entered the stoma. It is interesting to note that these lobes, as well as the first one formed in the substomatal cavity, all have distinctly thickened walls that stain like the spore wall, being green because of the combined effect of the methylene blue and the yellow wall pigment. This indicates that the infection process took a considerable time and that even in the substomatal cavity conditions were not entirely favorable.

Three pairs of nuclei are present in the hypha, all in the partly expanded state typical of nuclei in the vegetative mycelium. The endosphere is plainly seen with the buffer stain, but when the Feulgen stain is employed the even distribution of chromatin throughout the nucleus makes it indistinct. The exact condition of the hyphal nuclei varies considerably: there may be a fairly large ectosphere, containing most of the chromatin; or all the chromatin may be in the endosphere, and the ectosphere visible only as a small hyaline zone. Rarely they are completely unexpanded, but, in general, it may be said that they are partly expanded unless performing some special function.

In order to establish itself, the mycelium must send haustoria into the host cells. The first certain indication that a haustorium is to be formed by a hypha in contact with a host cell is the reversion of the nuclei to the unexpanded form (fig. 9, 12). This type of reversion is brought about by the retreat of such chromatin as is in the ectosphere into the endosphere. The ectosphere meanwhile contracts to meet the membrane of the slightly enlarging endosphere. The altered appearance is very striking with the buffer stain, but, of course, is not apparent in Feulgen preparations. An extremely slender penetration thread is formed, and, at its end, a lobe into which the nuclei pass. At the left of figure 9 the first of the two nuclei has passed almost completely into the lobe. The haustorium nuclei typically preserve their unexpanded form, though a suggestion of a small outer sphere is sometimes seen, as in figure 11.

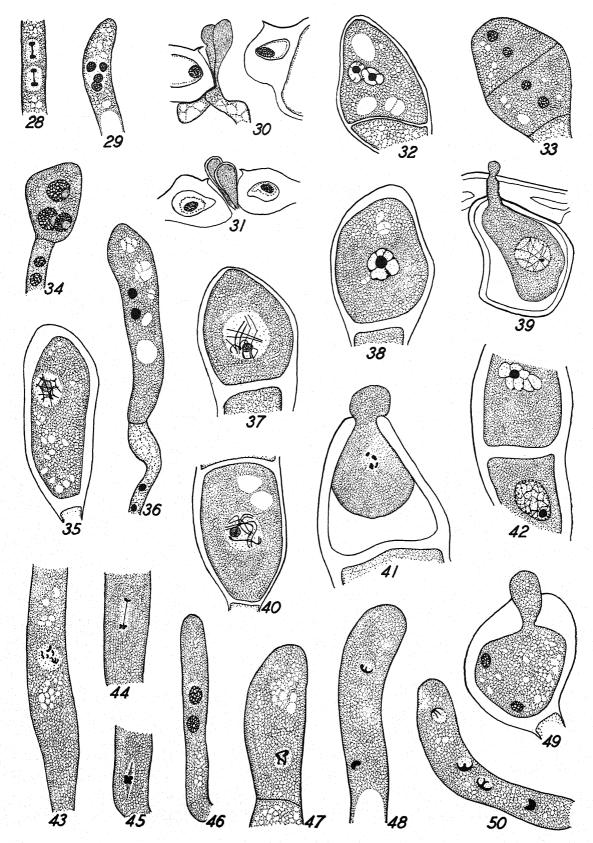

A mature haustorium of *Uromyces Fabae*, with unexpanded nuclei, is shown in figure 10, closely investing and distorting the host nucleus. That the haustoria of this species are attracted in some way toward the host nuclei seems to be quite certain. They may penetrate the cell at any point, but once they have entered it they very soon become directed toward the nucleus. One occasionally sees two or three widely separated haustoria converging upon a centrally located nucleus. The most logical explanation for this seems to be that certain elaborated food materials must be obtained from the host nucleus, from which they diffuse, rather than merely from the cytoplasm.

Clear and easily interpreted division figures in the mycelium are difficult to find. Those that have been found indicate that these divisions are similar to those to be described in more detail in connection with the basidium. At the right of figure 14, a pair of nuclei is seen in late prophase with the chromosome contraction completed. Of the four remaining nuclei the two in the center are partly superimposed and are sliding past each other to restore the pairing of compatible strains. The extra space provided by the new hyphal branch above has allowed this to take place without the usual amount of distortion. Eventually two of these nuclei would have moved out into this new branch. When the nuclei are still in the unexpanded state they seem to be very fluid and become greatly distorted in the process of rearrangement. This is shown in figure 15, which is the type of figure commonly regarded as a conjugate telophase. Such an interpretation looks upon the two stationary nuclei as persistent, discharged "nucleoli." The partly expanded nucleus does not discharge its endosphere, however; the endosphere merely increases slightly in size, and the division starts within it, and later its membrane breaks down.

When four nuclei are seen in a cell just after division, it does not seem possible to tell from the degree of their expansion whether the rearrangement has taken place. If, however, the nuclei are very closely associated in pairs, as in figure 16, it is probably safe to assume that it has already occurred, for sister nuclei are mutually repulsive and so would be separated by at least the length of the spindle.

Figure 13 shows a pair of hyphal nuclei in anaphase. The divisions in the two nuclei usually proceed at exactly the same pace, as in this example.

When a new uredinium is formed, a number of thin-walled but turgid buffer cells are produced first

at its center and later at its edges for the purpose of lifting the epidermis and allowing unhindered development of the spores. The nuclei of these cells stand out in sharp contrast to those of the spores (fig. 17), being only very slightly expanded.

Disregarding the general morphology of the uredinium, we turn next to the divisions leading to the production of the spores. These are two in number: that by which the basal cell cuts off the spore mothercell and that by which the mother-cell is separated into spore and pedicel. These divisions have never been followed accurately, only the telophase usually being depicted. They are considerably more difficult to distinguish than those in the aecium, which will later be described in detail, but it is thought that they are essentially similar. The nuclei of both the basal cell and the spore mother-cell become completely expanded and so must almost certainly divide in the manner typical for this form, with the prophase chromosomes lying outside the endosphere in the ectosphere cavity. The spore mother-cells are successively budded off from the basal cell, as shown in figure 18, a new one being formed laterally before the pedicel of the previous spore has disappeared.

Figure 19 shows the nuclei in prophase in a spore mother-cell; the chromosomes have contracted slightly, and the ectosphere membranes and the endospheres have disappeared. A basal cell in anaphase is shown in figure 20; the spindles appear slightly shorter than they actually are, because they are not in the exact plane of the slide. The telophase and nuclear reconstruction can be clearly followed and, together with similar stages at other parts of the life-cycle, supply further evidence that the endosphere is very different from the nucleolus as it is properly understood. The separating chromosome groups become arranged more or less in a square and take on the appearance of a flat plate from which delicate strands are often seen to trail (fig. 21). They move considerably farther apart than the length of the spindle, and then (fig. 22) curved processes of chromatin are thrown out from the chromatin plate to cut out a sphere from the cytoplasm. There are apparently about four of these processes; this suggests that they may actually be the chromosomes returning to the metabolic state. They soon anastomose to form a reticulate hollow sphere.

In these divisions there is usually plenty of room for the spindles to be formed side by side, and this position is commonly attained before telophase starts. Occasionally the orientation apparently fails to take place, and the nuclei are partly reorganized before pairing at the top and bottom of the cell. Figure 23 probably represents such a rearrangement; though, this being a haematoxylin preparation, it is not possible to be certain that the spherical bodies are not endospheres and the two bodies in the center imperfectly differentiated prophase figures. One argument against such an interpretation is that during the actual divisions it is usually impossible to get the cytoplasm as clear as in this figure and still keep the nuclei black.

After the second division, the two pairs of nuclei behave differently. Those in the pedicel remain unexpanded or virtually so, part of the chromatin passing into the central part of the nucleus and giving it an evenly reticlulate appearance (fig. 25). The chromatin of the spore nuclei may all remain for a short time at the periphery of the sphere cut out from the cytoplasm, or some of it may pass into its center; but before long a large ectosphere is delimited from the cytoplasm by the formation of vacuoles that gradually coalesce (fig. 24), the chromatin passes out toward the periphery of this, and the endosphere is soon left without any. The chromatin may nearly all pass to the outer membrane of the ectosphere or it may remain in a regular reticulum (fig. 25).

An interesting phenomenon rather frequently seen in *Uromyces Fabae* is the division of the pedicel nuclei. Four reformed nuclei have been found only once (fig. 29), and the telophases (fig. 28) are not common, but the earlier stages have been found

A.

rather frequently in some collections. A late prophase is shown in figure 26, and an anaphase in figure 27. These figures stain well with the buffer method and are clearer than those usually obtained in the hyphae. This is partly explained by the small amount of ergastic material found in these cells and partly, perhaps, by the scanty cytoplasm. The reason for this seemingly functionless division is not certain. The only apparent clue to its origin that the writer has been able to find is in Fromme's (1912) investigation of *Melampsora Lini*. He showed that the urediniospore pedicels of this rust are commonly two- or three-celled. The divisions in *U. Fabae* may be a relic of this condition.

Associated with the uredinial stage in some of the material of *U. Fabae* were rather numerous hyphal tips emerging from the stomata. These seem to have been short-lived, since nearly all those seen had been pinched off by the closing stomata, as in figure 30. The contents are amorphous in appearance rather than granular or reticulate, and so were presumably not living at the time of fixation. These hyphae are very similar in appearance to those seen by Andrus (1931) associated with the pycnia of Uromyces appendiculatus, and by Rice (1933) associated with the pyenia of Puccinia Sorghi. Both these writers considered them to be trichogyne tips. Ashworth (1935a) showed that such hyphae occur close to the uredinia or telia of several rusts, including some that are apparently homothallic. These findings clearly indicate that such hyphae, though they may possibly serve as receptive hyphae, are not to be regarded as specific female structures. Actually they seem to be formed wherever the mycelium is massed under the epidermis and their emergence is probably largely a matter of chance, though it may be influenced by the external environment. A careful examination of the ruptured epidermis over the uredinia revealed many such tips broken off and lodged in the stomata (fig. 31).

Allen (1935) described what she considered to be conidia cut off from the apices of stomatal hyphae of *Puccinia Malvacearum* and suggested that they might take the place of the pycniospores in this rust. As Ashworth (1931) showed fairly convincingly, however, that this rust is homothallic, and so not in need of such spores, it seems probable that what Allen saw were hyphal tips cut off in the manner here described.

The telium and basidium.—The development of the telium in Puccinia and Uromyces, with which we are chiefly concerned, is essentially the same as that of the uredinium. In Puccinia there is one extra division in the formation of the two-celled spores, but this division presents nothing new. The nuclei eventually become expanded before this final division, but they may remain unexpanded for some time (fig. 36), while the cell is increasing in size. The next stage of importance comes immediately after this final division in the formation of the teliospore, when the nuclei become expanded and fuse. There seems to be great variation in the rate of these processes, in

relation both to each other and to the development of the spore wall. Figures 33 and 34 form a remarkable contrast. Figure 33 shows a young spore of Puccinia Hieracii; here the formation of the ectospheres has not yet started, although the septum between the cells is complete. The teliospore of Transchelia fusca is also two-celled. In the example shown in figure 34 not only have all the nuclei become fully expanded, but those of the upper cell have already fused, although no sign of a septum could be seen. Figures 34 and 42 provide a further contrast. The nuclei of the lower cell in figure 34 have become completely expanded before fusion. In figure 42, representing a teliospore of Puccinia Malvacearum, the two nuclei of the upper cell have fused, although expansion is not nearly complete.

The process of nuclear expansion is very clearly seen in the teliospore. As already mentioned it is initiated by the formation of a number of vacuoles around the unexpanded nucleus. The irregular shape seen in the upper cell of figure 42 is rather exceptional, but slightly lobed outer zones, such as are shown in figures 32 and 38, are commonly seen. The vacuoles gradually coalesce and the newly-formed ectosphere takes on a smooth periphery. At the same time, the chromatin gradually leaves the endosphere, passing along the protoplasmic strands in which it is supported. Finally the chromatin becomes disposed in a typical open reticulum, as in the lower cell in figure 42.

The delicacy of the chromatin strands makes difficult the exact identification of the early stages of the first meiotic division in the fusion nucleus, but some have been clearly recognized. During the expansion the endosphere decreases somewhat in size. It may continue to dwindle and to be almost completely disintegrated at the start of prophase (fig. 39); but as a rule it persists almost unchanged until the pairing of the elongated chromosomes is complete. The endosphere then disintegrates rather rapidly, as is shown both by its decreased size and by its decreased stainability.

The first indication of the start of prophase is the change of the chromatin from a reticulum to a number of strands that at first seem to have no wellordered arrangement and whose individuality is not clear (fig. 39). A slightly later stage is shown, for Uromyces Fabae, in figure 35. In this spore the threads are more distinct, but they seem to be distributed at random throughout the ectosphere. Their exact number cannot be ascertained, since it is often impossible to distinguish two adjacent threads from a single sharply bent one. The next recognizable stage is the zygonema, of which several good examples have been found in Puccinia Malvacearum. In figure 37 the number of chromosomes is in doubt, because the pairing is not complete and the threads are greatly contorted toward the basal side of the nucleus. In figure 40, however, there seems to be little doubt that the number of pairs is four, since all the ends lie free from one another. The exact length of the threads cannot be determined, since their convolutions are in both the vertical and horizontal planes, but they are surprisingly long. One pair seems to be about 8  $\mu$  in length, a second about 6  $\mu$ , and the others from 4 to 5  $\mu$ .

The chromosomes apparently contract very abruptly after pairing, for it has not been possible to find the next prophase stages with the exception of an occasional rather indistinct diakinesis. Actually the chance of discerning any doubleness of the threads in the missing stages with such unfavorable material is small. Figure 41 shows the nucleus about to pass into the basidium in what is evidently diakinesis; there are two small and two relatively large clumps of chromatin.

As far as could be judged from the material examined, the stage at which the nucleus leaves the teliospore varies somewhat with the species. In Melampsora Bigelowii it generally seems to migrate before the pairing of the chromosomes (fig. 39). In Puccinia Malvacearum it generally passes into the basidium between zygonema and diakinesis, whereas in Uromyces Lespendezae-procumbentis division may become far advanced in the spore and may even be completed within it (fig. 49). It is not certain that this is an inherent tendency of the species, since it may conceivably be influenced by the physiological state of the material at the time of germination.

The stage shown in figure 43 is not very easily identified, but since the individual chromosomes are distinct it is presumably somewhat later than that seen in figure 41, and immediately precedes the formation of the spindle. The metaphase itself is clearly seen in material heavily stained with haematoxylin (fig. 45), as is the succeeding anaphase, but the heavy stain required to bring out the spindle usually makes a chromosome count impossible by causing the chromosomes to appear clumped.

In late anaphase it often looks as though there were only two chromosomes going to each pole, and this effect in particular seems to account for the chromosome count of two given by Sappin-Trouffy for all species examined by him. Careful focussing reveals that each body is actually two superimposed chromosomes. This is shown in the late anaphase seen in figure 44. At the upper end of the spindle there seems to be merely a two-lobed chromatin mass; but the lower end is viewed somewhat obliquely, and it is seen that there are four bodies arranged approximately in a square, though even here only two of the group could be brought into focus at the same time.

Occasionally end views of anaphases have been seen in sections of germinating Puccinia Malvacearum sori, and these confirm the arrangement of the chromosome groups in a square. Such views do not lend themselves to illustration, but it is possible to draw the two groups separately, which shows that there are two very small chromosomes and two slightly larger ones in each group. The larger ones, allowing for the foreshortening effect that obtains when they do not lie quite parallel to the slide, have been calculated to be about 0.5–0.7  $\mu$  long, and the

shorter ones seem to be about 0.25  $\mu$  long. The diameter of each seems to be about 0.20–0.25  $\mu$ .

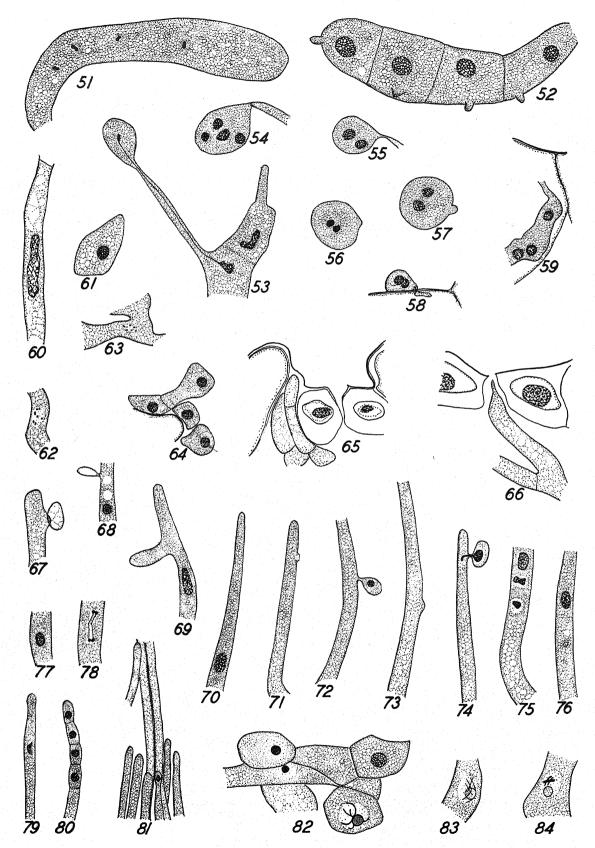

It is at first difficult to see how such long threads as those shown in figure 40 can contract in anaphase to the dimensions indicated. The explanation probably is that the apparent diameter of the prophase threads is much greater than the true diameter. Two factors may contribute to such an effect. In the first place, the diameter is increased by the adsorption or precipitation of dye and, perhaps, other material upon the chromosomes. Though both the long and the contracted chromosomes will be affected, the proportionate increase will be far greater for the thin thread. In the second place, the diameter of the stained prophase threads, though just above the limit of actual vision, is considerably below the limit of true resolution. With green light the resolving power of an objective with a numerical aperture of 1.3 is about 0.2  $\mu$  with a full condenser cone. Objects appreciably narrower than this are usually invisible if lightly colored, but if deeply stained they will be discernible and will appear considerably broader than they really are. If the prophase threads contract without change in volume, their calculated diameter when at their maximum length is about 0.04 μ. The contraction probably is accompanied by some loss in volume, but even so the true minimum diameter must be considerably less than 0.1  $\mu$ .

No well-defined centrosomes have been seen in any of the forms studied, though small dots are sometimes visible at the ends of the spindle in haematoxylin preparations. These may be centrosomes, but it seems possible that they are simply optical effects. The spindle fibers, even when heavily stained, are so far below the limit of resolution that they appear gray; but where they meet at the end of the spindle they may build up to a size approaching the limit of resolution and so appear black.

Allen (1933b), in her study of the germination of the teliospores of Puccinia Malvacearum, suggested that the haploid number was five. The chromosomes are so small that it is often impossible to be certain whether one is looking at one relatively large, or two adjacent, very small ones. The writer's observations, gleaned from both prophase and anaphase figures, indicate a haploid number of four for this species and for Uromyces Fabae, U. Hyperici, Puccinia Sorghi, and Melampsora Bigelowii. Observations on other species do not warrant an estimate.

The groups of chromosomes usually move far apart during telophase (fig. 48) and cut out new spheres from the cytoplasm in the manner already described. The nuclei become reticulate but remain unexpanded (fig. 46). To judge from the small number of metabolic nuclei seen at this stage, the interphase must be short.

The second division is typical of that of unexpanded nuclei in other parts of the life-cycle. In the prophase seen in figure 47, chromosome contraction had probably already commenced, since the threads are rather thick; but in this division, and in all the mitotic divisions, it seems that the prophase chromo-

somes attain only about half the length of those seen in the fusion nucleus.

The period at which the first septum is laid down in the basidium varies greatly, but it has never been seen to form until all traces of the spindle have disappeared. It may be formed at the time of the prophase of the second division (fig. 47), but it is commonly delayed until the telophase (fig. 51), or even nuclear reconstruction following this division (fig. 50). Nuclear reconstruction is similar to that following the first division, and the septa between the products of the second division form promptly, resulting in a four-celled basidium with unexpanded nuclei. For some reason these nuclei seldom stain strongly even with haematoxylin or the Feulgen stain, and occasionally they are indistinguishable. Not only is the ergastic material, on which the buffer stain is dependent, almost entirely absent, but the chromatin seems to be in a more delicate reticulum than usual, and the threads may be below the limit of vision.

The formation of the sterigmata starts as soon as the basidium becomes four-celled. Their length depends largely upon whether or not there is water upon the leaf surface. If the basidium is almost completely immersed, the lower sterigmata usually become very long, in order to raise the spores clear of the surface. The nucleus passes into the spore before the latter attains its full size, and becomes greatly constricted in passing through the apex of the sterigma. When the latter is longer than usual, this attenuation of the nucleus may be very remarkable (fig. 53).

Allen (1933b) has already shown for Puccinia Malvacearum that the basidiospore nucleus divides

before the germination of the spore. The present study has confirmed this and has shown the same to be true of Uromyces Lespedezae-procumbentis and Melampsora Bigelowii. Figure 56 shows the telophase of the division in M. Bigelowii, and figure 57 shows the two unexpanded nuclei. In U. Lespedezae-procumbentis the division commonly occurs before the spore is discharged (fig. 55), or even before it reaches its full size. On one occasion a quadrinucleate spore was found in this species (fig. 54). Since the basidium was not intact, it was not possible to determine whether this represented an extra division or whether two nuclei from the basidium had passed into the spore.

The monokaryon thallus.—The basidiospore germinates by forming a very short germ-tube and an appressorium and then enters the host by sending a slender process directly into an epidermal cell (fig. 58). One or more nuclear divisions normally occur after penetration; the intracellular hypha accordingly contains several unexpanded nuclei (fig. 59). Then septation occurs, and at least one of the cells pierces the inner wall with a slender thread, and its nucleus passes into the intercellular space to initiate the normal intercellular mycelium. Only then do the nuclei become partly expanded.

The nuclei of the monokaryon mycelium are essentially similar to those of the dikaryon. They range from the greatly extended form illustrated in figure 60, commonly found in old hyphal cells, to the unexpanded or scarcely expanded forms seen in the pseudoparenchyma cells bounding the aecial primordium (fig. 61) or the pycnium (fig. 64). Divisions are even harder to distinguish than in the di-

karyon, where one of the two nuclei may be so oriented that the stage can be seen. Two anaphases, from close to the base of a young accium of *Uromyces Fabae* in which diploidization was just starting, are shown in figures 62 and 63. These will be further discussed in connection with the diploidization process.

The monokaryon haustoria are formed in essentially the same way as those of the dikaryon mycelium and, except for being uninucleate, are essentially similar in appearance. A single binucleate haustorium was found in a monokaryon pustule of Uromyces Fabae, but this is clearly to be regarded as an abnormality. The nuclei normally retain their unexpanded form, but a hyaline zone is sometimes seen around them, which probably indicates the initiation of the ectosphere. In very old haustoria they often take on an irregular form and may increase in size.

The pycnium and the introduction of pycniospore nuclei.—The pycnial stage is, of course, particularly interesting because of its importance in connection with the process of diploidization. Considerable attention was therefore devoted to it in an effort to find out more about the mechanism by which pycniospore nuclei of the compatible strain are brought to the aecial primordium. While this was not completely successful, some additional information was obtained that may help to lessen the existing confusion. A great deal of material of Puccinia Sorghi and Uromyces Fabae was examined, and smaller amounts of material of U. Lespedezae-procumbentis and U. Hyperici. The two latter, and U. Hyperici in particular, have smaller nuclei than the other species and so are less suitable.

Particular attention was devoted to the occurrence of emergent hyphae, whether of the stomatal, epidermal, or ostiolar type. The observations made add weight to the writer's opinion that the stomatal and epidermal hyphae are formed largely by chance. Stomatal hyphae were occasionally seen close to the pycnia, but always with their tips crushed by the stomatal movement (fig. 66). Hyphae pressing up between the epidermal cells were often seen (fig. 65), but never breaking through the cuticle. The remnants of both types can often be seen in the crushed epidermis bordering the ostiole of the pycnium, which strengthens the belief that they are the result of a massing of mycelium beneath the epidermis and are not specialized organs.

Several times whole pustules of Puccinia Sorghi and Uromyces Fabae, in which diploidization had just started, were carefully examined, and were found to be without any emergent hyphae, other than those from the ostioles. Although these epidermal and stomatal hyphae, if better developed, may serve as supplementary receptive hyphae, it seems clear that in these two species the ostiolar hyphae are considerably the more important.

Craigie (1933) and Buller (1938) distinguished two types of ostiolar hyphae: the stiff, tapering, marginal paraphyses, and thin-walled, flexuous hyphae with blunt ends, varying greatly in length and abundance and emerging more nearly from the middle of the ostiole. Only the latter were considered to be receptive. Their origin has not been clearly demonstrated, but it is logical to believe that they arise from lower on the wall of the pycnium than do the

marginal paraphyses.

Hunter (1936), in a morphological study of the pycnia of the Melampsoraceae, saw groups of such hyphae arising from the center of the pycnium in a number of species. She also pointed out that Colley (1918), to whom their function was naturally obscure, saw similar hyphae in Cronartium ribicola. In this family there are no paraphyses, and there is every reason to believe that Hunter's suggestion that these are receptive hyphae is correct. Moreover, free-hand sections revealed pycniospores clinging to them. No such large groups of hyphae seem to arise from the bases of the pycnia in the Pucciniaceae, but individual hyphae, or groups of two or three, may occasionally be found. Figure 81 shows parts of two old hyphae and the tip of a young one arising from the center of the base of a pycnium of Uromyces Lespedezae-procumbentis. The older hyphae could be followed to the ostiole in the adjacent section, but could not be traced to the end. If a hypha passes completely through the congested region within a single section it may be possible to trace its entire length, but as a rule only free-hand sections permit determination of the full extent of the apical part of a long emergent hypha. These, unfortunately, are virtually useless for following it through the ostiole. That the flexuous hyphae do not always arise from the base of the pycnium in the species studied is evident, however, for many pycnia, with hyphae that are definitely of the flexuous type, show no hyphae arising from lower than about halfway up the sides of the cavity. The lowest of such hyphae usually emerge approximately in the center of the ostiole.

Not all writers have been able to distinguish the two types of ostiolar hyphae, a fact that is partly explained by the rarity with which a complete hypha of any great length will occur intact in a paraffin section; but the problem is further complicated by the frequent lack of a sharp distinction between the two types. In all the species studied, the writer found that if all the hyphae in a central section were drawn, there was nearly always a complete gradation from the typical paraphysis (fig. 70) at the edge to the blunt and often branched hypha toward the center. It is not possible to divide them into the two clearly separate types shown by Buller (1938) in his sketch of the pycnia of *Puccinia graminis*.

The most satisfactory stain for this phase of a cytological study of the rusts is unquestionably Feulgen's. The pycniospores stain very poorly with the buffer stain and not much better with haematoxylin. The fact that the cytoplasm of the ostiolar hyphae does not stain well adds further to the difficulty. The apical parts are invariably light pink when the buffer stain is used. This reaction suggests that the cytoplasm contains some of the ergastic material

that is normally found in the nuclei but is absent from those of the pycniospores. They are also often slightly tinged with pink when the Feulgen stain is used and never take the counterstain as strongly as does the vegetative mycelium. There is evidently some substance present that gives an aldehyde reaction; but whether it is really a nucleoprotein or merely some ergastic substance, perhaps formed as a result of the altered environment of the hyphae, is not clear.

The nuclei of the pycniospores are spherical and unexpanded (fig. 72, 80), those of the emergent hyphae elliptical and partly expanded (fig. 69, 70). The nuclei of the pycniosporophores are sometimes expanded to some extent, but are very often compact and apparently unexpanded (fig. 77). This compactness is explained by the fact that they divide so frequently to produce new spores that they have little time to expand. Prophase figures with the chromosomes lying approximately parallel (fig. 79) can be found, but the metaphase and anaphase stages have not been clearly distinguished. Telophases stain very clearly and may be found in almost any section. For some reason the spindle, just before it disappears, is often sharply bent (fig. 78).

Hunter (1936) describes the pycniospores as being typically catenulate in the Melampsoraceae. A tendency toward this habit was occasionally observed in *Uromyces Lespedezae-procumbentis* (fig. 80), but generally, in the species studied, one spore is discharged before the next one starts to form.

Very few convincing examples of pycniospores attached to receptive hyphae were found. Spores were often seen in contact with the hyphae, but it was only occasionally that definite evidence of union could be found. Figure 67 shows an empty spore of Uromyces Fabae attached to a large papilla near the tip of a blunt hypha. Figure 74 shows another fusion in U. Fabae, in this case with a slightly tapering hypha. This preparation was not well-stained, but the nucleus appears to be starting to migrate into the hypha. The fusion papilla is in this case much smaller. Figure 68 shows an empty and partially collapsed spore of Puccinia Sorghi attached to a slightly tapering hypha. The small rounded nucleus is probably that of the spore, the hyphal nucleus being lower down and out of the section. Well-marked vacuoles, such as are seen in this figure, often accompany great activity in a cell, and these suggest that nuclear migration had only just occurred. Figure 72 shows another fused pycniospore of P. Sorghi, this time with the nucleus still in the spore.

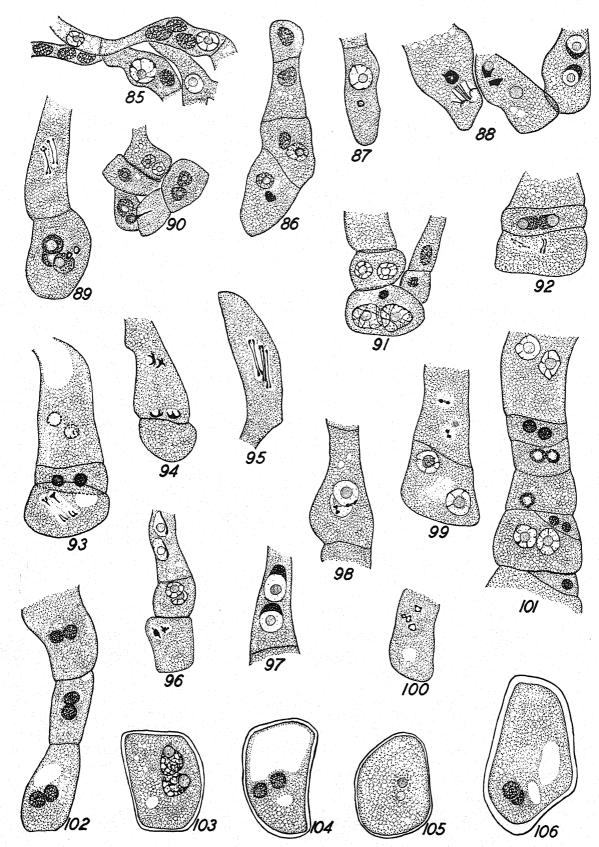

Branched hyphae (fig. 69) are not uncommonly seen in *P. Sorghi*. They seem to be essentially similar to those shown by Buller (1938) in his figure 3, but nothing approaching the length indicated by him has been seen in either paraffin or free-hand sections of any of the species examined. The length of these hyphae may be dependent upon the environmental conditions. Pycniospores were on several occasions seen in contact with the tips of these short side branches but were never so oriented that it could be

definitely decided whether they had actually fused to them or were merely in chance contact.

Two other evidences of the introduction of pycniospore nuclei through the ostiolar hyphae were found in material fixed a few hours after mixing the nectar. The first of these is the occurrence of small papillae on the more flexuous hyphae. These may appear rounded (fig. 73), or the top may be flattened and extremely delicate (fig. 71). What is evidently the same structure as this last may be seen in surface view. By focussing very carefully upon the upper or lower wall of a hypha, using not too strong a light, small circular bright areas may occasionally be seen. Figure 76 shows the typical size of such a spot: its actual appearance is beyond the scope of a line drawing. These thin areas and papillae evidently represent places at which pycniospores were attached at the time of fixation. The second additional evidence is the occasional presence of several nuclei in a hypha. They are likely to be somewhat distorted and abnormal in appearance, but react characteristically to the Feulgen stain. Two such nuclei are seen below the hyphal nucleus in figure 75. The abnormal shapes may be due to violent streaming associated with the passage of the introduced nuclei past the hyphal nucleus or may indicate the beginning of nuclear division. Since plurinucleate ostiolar hyphae are never found in pustules guarded from insects prior to mixing the nectar, it is evident that these are actually pycniospore nuclei.

The aecial primordium.—The development of the aecial primordium usually starts considerably before the first pycnia start discharging spores, but the degree of differentiation reached at the time of diploidization depends on the time that elapses between opening of the pycnia and mixing of the nectar. In nature the degree of differentiation is often very considerable, but if diploidization is effected very early, it may be slight. As a rule it is possible to distinguish the basal "fertile layer" and the outer "sterile layer," to use the terminology of the earlier writers. This outer tissue of very vacuolate cells has already served its purpose by thrusting aside and crushing the chlorenchyma cells, and it then gives up most of its nutritive material to the more active parts of the thallus and is destroyed when spore formation starts. It is possible for diploidization to start before this differentiation is evident, however, and this may partly account for the lack of agreement about the precise point of formation, in the young accium, of the first dikaryon cells.

At the base of the primordium typical hyphal cells are seen, usually with slightly expanded nuclei. As we progress toward the apex (downward in the drawings), we find a more or less pseudoparenchymatous structure in which it is often impossible to tell which are the consecutive cells of a hypha. The first of these may have almost unexpanded nuclei, but those a little nearer the epidermis usually have completely expanded nuclei at the time when diploidization starts. Finally, directly beneath the epidermis, lie the "sterile" buffer cells whose nuclei are

also nearly unexpanded. In a partly differentiated primordium the change of form of the nuclei can be studied. Figure 82 shows a group of cells from such a primordium of Puccinia Sorghi. The two dense nuclei at the left are completely unexpanded, though the hyaline zone surrounding each suggests that expansion might be about to start. At the right above is a partly expanded nucleus the chromatin of which is too evenly distributed for the boundary of the endosphere to be evident with the Feulgen stain. At the right below, nearest the leaf surface, is a nucleus in which the fully expanded form is being adopted. Here a large ectosphere has been delimited and the chromatin is passing out to its periphery along delicate protoplasmic strands. When the process is complete, most of the chromatin is usually very finely dispersed about the ectosphere membrane and may be only barely discernible with the Feulgen stain. This makes it very apparent that much more than chromatin is stained in the reticulum of the expanded nucleus when haematoxylin is used.

If diploidization is delayed beyond the time when these cells have become fully expanded, the primordium may continue to enlarge to some extent. This continued growth gives us an opportunity to observe the division of the expanded nucleus. The chromatin being all in the ectosphere, the division figure takes shape, not in a slightly enlarged endosphere, but in the ectosphere cavity. Figure 83 shows the chromosomes at about their maximum length, overlying the endosphere. Figure 84 shows a later prophase with the chromosomes partly contracted. The division of the expanded nucleus will be taken up in detail later, in connection with the formation of the aeciospores.

Diploidization.—If the nectar is mixed and compatible nuclei are introduced as soon as the pycnia

open, diploidization may start before the nuclei with which they are to pair are fully expanded. When, on the other hand, mixing of the nectar is delayed for some time, the majority of nuclei in the base of the primordium become fully expanded. The state of the primordium at the time of diploidization can thus be seen to have some bearing on the ease with which the thallus nuclei can be distinguished from those that have been introduced, for the migrating nuclei are unexpanded. This point is clearly seen if figures 85 and 86 are compared. Figure 85 shows a group of cells at the base of a primordium of Puccinia Sorghi, fixed twenty-four hours after the nectar was mixed. In each cell there is one fully expanded thallus nucleus, with a clear green endosphere supported by a few delicate strands in the large ectosphere with almost all the chromatin disposed on its periphery. Sharply contrasting with these expanded nuclei are a number of evenly reticulate, smaller nuclei that take the Feulgen stain very strongly. Three of these are to be seen in the cell at the left; four, partly superimposed, are in the cell at the upper right, and there is one in the center cell below.

Figure 86 shows a single hypha from a primordium of Uromyces Lespedezae-procumbentis in which diploidization had progressed to about the same extent. The whole development of the pycnial and aecial stages of this rust seems to be much slower than that of P. Sorghi. The retardation includes not only the time between the opening of the first pycnia and the full differentiation of the primordia, but apparently even the time taken by the introduced nuclei in reaching the primordium. In no instance was any diploidization observed within twenty-four hours of mixing the nectar, while in P. Sorghi the minimum is apparently slightly under ten hours.

Fig. 85-106.—Fig. 85. Aecial primordium of P. Sorghi twenty-four hours after mixing nectar; numerous unexpanded introduced nuclei present, contrasting strongly with the expanded thallus nuclei. Feulgen. F. A. A.-Fig. 86. Hypha in partly diploidized accium of U. Lespedezae-procumbentis. The terminal and subterminal cells each have one unexpanded and one almost fully expanded nucleus. Feulgen. F. A. A .- Fig. 87. Cell in P. Sorghi primordium twentyfour hours after mixing nectar; fully expanded thallus nucleus and small nucleus evidently in late prophase; the latter probably dividing to supply a nucleus for an adjacent cell. Feulgen. D. G.—Fig. 88. Conjugate divisions in partly diploidized aecium of U. Fabae; early prophase at right; later stage at center with ectosphere membrane broken down; at left, intermediate prophase stage, the four chromosomes in each nucleus still elongate and the two nuclei forming mirror images, while above there is a third nucleus in the cell. Feulgen. F. A. A .- Fig. 89. Same aecium as figure 88; terminal cell contains three expanded nuclei, while the fourth has apparently just divided to supply a nucleus to an adjacent cell. Feulgen. F. A. A.—Fig. 90. Nuclear migration at base of P. Sorghi aecium forty hours after mixing nectar. Feulgen. F. A. A.-Fig. 91. Chain of dikaryon cells in young U. Fabas accium with extra, unexpanded nucleus in one cell and monokaryon hypha adjacent. Feulgen. F. A. A.-Fig. 92. Late anaphase in U. Fabae aeciospore mother-cell, the spindles not yet parallel. Feulgen. F. A. A.—Fig. 93. U. Fabae aeciospore column, showing early telophase in spore mother-cell; the spindles are parallel. Feulgen. F. A. A.-Fig. 94. Late telophase in U. Fabae basal cell, showing formation of endospheres of new nuclei. Feulgen. F. A. A.—Fig. 95. Early telophase in trinucleate basal cell of  $\bar{U}$ . Fabae; this one originated deep in the primordium, but the majority are formed by equal-cell fusion of a dikaryon with a monokaryon cell. Feulgen. F. A. A.—Fig. 96. Early prophase in basal cell, and early anaphase in spore mother-cell of P. Sorghi. Feulgen. D. G .- Fig. 97. Early prophase in basal cell; same preparation as figure 96.—Fig. 98. Anaphase in P. Sorghi basal cell; endospheres and membranes of ectospheres visible at later stage than usual. Feulgen. D. G.-Fig. 99. Similar stage to last, but ectosphere membranes and one endosphere have disappeared; second endosphere is disintegrating. Same preparation as figure 98.—Fig. 100. End of anaphase in P. Sorghi basal cell; spindles not yet parallel. Feulgen. F. A. A.—Fig. 101. U. Fabae acciospore chain, showing variation in nuclear form. Feulgen. F. A. A .- Fig. 102. Chain of columnar cells in U. Fabae aecium. Feulgen. F. A. A.—Fig. 103. U. Fabae acciospore showing distinct granule, surrounded by "heller Hof," in each endosphere. Haematoxylin, with prolonged destaining. F. A. A.-Fig. 104. Peridial cell of U. Fabae. Haematoxylin. F. A. A.—Fig. 105. Peridial cell of U. Fabae with endospheres showing distinctly and chromatin indistinct. Granule visible in each endosphere. Buffer. F. A. A.-Fig. 106. Peridial cell of U. Fabae. Feulgen. F. A. A.

Although there is little doubt which are the thallus and which the introduced nuclei in the two binucleate cells in this figure, it would have been difficult to make such a distinction for the other cells had they contained more than one nucleus; and, indeed, one cannot be sure that the nucleus in the top cell, which runs out of the section, is actually the thallus nucleus.

There is no sign in figures 85 and 86 of any partial dissolution of the septa, nor was this seen in any material of this stage. The unexpanded nucleus is evidently adapted to passing through minute openings. The septal pores, though not usually visible in the mycelium, can be seen to be about  $0.15-0.20~\mu$  in diameter in the spores. Such an opening is probably ample for its passage, since that in the base of the haustorium is usually considerably narrower. In preparations steeped first in tannic acid and then in ferric chloride to give intensely stained walls, the septal pores in the older, vacuolate hyphae are seen to be filled by small plugs of undetermined composition. These are presumably destroyed or displaced by the migrating nuclei.

It will now be seen that the introduced nuclei can often be distinguished from the thallus nuclei in the ostiolar hyphae and at the base of the young aecium. It must be confessed, however, that the writer has not been able to recognize them in the vegetative hyphae leading from the pycnium to the primordium. Several factors combine to make this difficult. In the first place, the nuclei diploidizing a given primordium may often have entered through one of several pycnia. Secondly, the connecting hyphae do not run directly to the primordium, but meander so much that it is difficult to trace them from section to section. A third factor is the indistinctness, with the most useful cytological methods, of many of the septa; this makes it difficult to decide whether two nuclei are actually in the same cell or not. Finally there is the variability in appearance of the hyphal nuclei, which makes certain distinctions very difficult.

It is also suspected that the introduced nuclei pass through the connecting hyphae very rapidly, a behavior that would lessen the chance of finding them. There is a strong possibility that these nuclei divide in the receptive hyphae, as is suggested by their distorted appearance and by the presence of two or three of them in a single hypha while adjacent hyphae contain none. Such divisions would tend to retard their movements. It is probable, however, that no such divisions occur in the journey from the pycnium to the edge of the primordium. Since the ground mycelium through which they pass is certainly not diploidized and no signs of such divisions have been found, there appears to be nothing to delay them.

When the edge of the primordium is reached, the nuclei evidently divide very freely. Divisions have occasionally been seen at the extreme base of primordia in which diploidization was just starting (fig. 62, 63). It is not likely that the thallus nuclei in this position would undergo division. The point cannot

be tested, however, for although early stages of the division might be found and might prove to belong to the unexpanded nuclei, it is quite possible that the thallus nuclei in this region would be only partly expanded. Divisions of the diploidizing nuclei at the extreme base of the primordia are also suggested by the finding of several in a single cell, while adjacent cells of the same hypha contain none (fig. 85). It is improbable that nuclei of the same strain, and therefore mutually repulsive, would complete their migration in such close association instead of becoming widely scattered.

Complete diploidization of the primordium is apparently effected in several ways. It is started by the introduced nuclei continuing their passage through the hyphae by which they entered and pairing up with the expanded nuclei of the enlarged cells toward their apices. Several cells of such a hypha may be diploidized (fig. 86), and those deep in the primordium then bud out and grow up beside those nearer the apex, so that all the spore mother-cells are cut off at approximately the same level. Thus one may partly account for the intertwining of the basal cells in the mature accium that makes the origin of the dikaryon so difficult to determine. This could give complete diploidization only if large numbers of nuclei entered the primordium at many different points, for the primordium is made up of a number of hyphae that separate long before reaching it.

Actually, diploidization seems to start at one or two points only, and subsidiary methods therefore are needed. One method that is certainly adopted is the migration of extra nuclei from cells such as that at the upper right of figure 85 to cells in adjacent hyphae. Thus one of the introduced nuclei in the cell just referred to might very well migrate into the monokaryon cell directly below it. Such migrations would certainly be through narrow pores, for as long as the nuclei remain only partly expanded, they can easily revert to the unexpanded form, as when a haustorium is formed; and once the migration is completed, the point at which it occurred cannot be seen. These two methods of diploidization probably account for most of the nuclear migrations of the type first described by Blackman (1904).

A third probable method, the existence of which is difficult to prove or disprove, might be regarded as an extension of the one just described. If the cell to be diploidized was not actually touching the one from which the diploidizing nucleus was to be supplied, it is reasonable to suppose that a fusion papilla would be formed to bridge the gap. If, however, all the adjacent cells had already been diploidized, either all of these supernumerary nuclei would have to be functionless, or, instead of short papillae, one or more hyphal branches would have to be formed from the cell, and the introduced nuclei would have to move up in them to diploidize cells further from the base of the primordium. Two findings support this hypothesis. One is the occurrence of monokaryon cells with unexpanded nuclei (fig. 91) at about the level of the basal cells, after the start of diploidization when all the thallus nuclei in this region normally are expanded.

The second finding supporting the formation of such branches is the occurrence of equal-cell fusions such as Christman (1905) first described. There has been a tendency, since the discovery of the function of the pycniospores, to discredit either the reality or the importance of these fusions. Andrus (1931), in particular, has attempted to dismiss them as mere vegetative fusions that occur before diploidization. There can be little doubt, nevertheless, that diploidization does occur to some extent by this method in many rusts. In Uromyces Fabae these fusions are seen infrequently but rather regularly in the apical part of the basal cell region. This region is always filled by pseudoparenchyma tissue before diploidization starts, so that the vertically oriented fusion cells must be of later origin than the supposed vegetative fusions. That the fusions of vertically oriented cells are really functional is indicated by the occasional finding of fusions which result in the cutting of trinucleate spore mother-cells (fig. 95). Several examples, corresponding very closely to those described by Fromme (1912) for Melampsora Lini, have been seen in U. Fabae; it is sometimes possible to see that they have arisen by the fusion of a dikaryon hypha with a monokaryon. The evidence provided by such irregular fusions leaves no valid reason for denying the reality of the more typical ones.

It is probable that the nuclei of the introduced strain are often expanded by the time such fusions occur, and since the expanded nucleus does not seem to be so well adapted to passing through a small pore as the unexpanded one, one would expect either migration through a wide pore or complete fusion of the upper parts of the cells. The migration of an expanded nucleus through a relatively wide pore, about  $0.6~\mu$  in diameter, is shown in figure 90. Whether such a pore would remain this size or whether it would gradually enlarge to give a typical fusion cell remains in doubt.

One other possible method of diploidization has been suggested by certain findings in the young aecium. Cells are occasionally found that contain an odd number of nuclei in various stages of development. Lamb (1935) seemed inclined to regard such discoveries as due to excessive application of pycniospores in artificial mixing of the nectar. The situation shown in figure 89 is not satisfactorily explained in this way. Here is a well-established basal cell with its nuclei in telophase. The cell shown below it is probably a second basal cell, since only two daughter nuclei of a spore mother-cell, namely those entering the new spore, become expanded. In this cell there are three expanded nuclei and what is evidently another nucleus in telophase. That so many nuclei should have migrated into this cell while only one remained in the cell through which they came seems improbable. The most feasible explanation is that this is a normal basal cell in which conjugate division had just taken place, and that one of the nuclei had been stimulated by the proximity of an adjacent monokaryon cell to undergo a further division, which would supply a nucleus to the latter. Similarly the small dense nucleus of the trinucleate terminal cell of figure 91 may have been formed by the division of one of the paired nuclei in this cell, providing for the diploidization of the adjacent monokaryon cell. In this instance, as was noted above, the unexpanded form of the nuclei in this monokaryon hypha suggests that they are of the introduced strain, so that the dividing nucleus would be of the thallus strain. The small nucleus seen in figure 87 is apparently in late prophase and is probably dividing in preparation for supplying a nucleus for an adjacent cell.

The division of one nucleus of a dikaryon cell without division of the second is not unprecedented. It occurs extensively during the progressive diploidization of a haploid hymenomycete mycelium, as shown by Buller (1930), and it presumably occurs to some extent in the diploidization of a haploid rust pustule by a diploid mycelium, as described by Brown (1932).

Sometimes, admittedly, nuclei are seen that have no obvious function. For example, in the left hand cell of figure 88 a compact nucleus is seen close to a pair of nuclei in prophase. A small projection of chromatin at one side of it suggests that it was either about to migrate at the time of fixation or had just done so, but its function is not clear, and it is possible that this actually is a superfluous nucleus.

The cytological evidence that the introduced nuclei divide freely to diploidize the primordium is strongly supported by the hybridization experiments of Newton, Johnson, and Brown (1930), who crossed various physiologic forms of Puccinia graminis Tritici. They found that if the pycnial nectar of several forms were mixed in a pycnium, different forms of the rust resulted from the different aecia, but that all the spores of a single aecium were usually identical. This highly important finding clearly suggests that the diploidizing nuclei in an aecium are typically the product of a single pycniospore. This does not necessarily mean that only one nucleus reaches the primordium. It is possible that the nuclei divide after entering the receptive hyphae and that two may reach the primordium by different routes. As already mentioned, diploidization has been seen to start in two different parts of the primordium. It would seem that the primordium's power of attraction is greatly diminished as soon as diploidization starts, so that only the practically simultaneous arrival of nuclei at different points can give rise to an accium whose spores are not all genetically alike.

The aecium.—Conjugate division of the fully expanded nuclei starts in some of the basal cells and even spore mother-cells before diploidization of the primordium is complete. These conjugate divisions have been followed in some detail with the aid of the Feulgen method, which seems to be the only satisfactory means of staining the dividing nuclei without interference from the abundant ergastic material.

The start of prophase is indicated by the chromatin becoming gathered to one side of the ectosphere, giving an effect reminiscent of the "bouquet" stage in the meiotic prophase of many animal cells. At first the nuclei tend to appear as identical images (fig. 96, 97). Later, the chromatin masses come to lie in adjacent positions, making the nuclei appear as mirror images, as is illustrated by the right hand cell of figure 88 and the middle cell of figure 92. Intermediate stages, of course, are seen in which no relation is apparent. From the first appearance of the mirror-image condition there is considerable variation in the appearance of the various stages, because the time at which the ectosphere membrane and the endosphere break down varies widely. The chromatin of each nucleus next resolves itself into four threads with a maximum length about half that seen in the fusion nucleus; that is to say, the largest chromosomes attain a length of about 4  $\mu$  and the shortest ones about 2  $\mu$ . In the left hand cell of figure 88 the situation is complicated by the presence of a third nucleus, but this cell offers a perfect example of the mirror-image effect already mentioned. The two nuclei are separated by a very fine film of cytoplasm. Just to either side of this film can be seen one of the long chromosomes. Beyond this, and approximately parallel to it in each nucleus, lies the second long chromosome, a little more widely separated from the first in the left hand nucleus than in the right. Toward the apical end of each nucleus is seen one of the short chromosomes, curved and lying at an angle to the long ones. The second short chromosome slightly overlaps the first and lies nearly parallel to the long ones. These mirror images clearly indicate that the dikaryon condition is preserved by two opposing forces acting on the two nuclei.

In the pair of nuclei just described the ectosphere has apparently disappeared, or, at any rate, is in the process of breaking down, and the endospheres have already disintegrated. Usually the endospheres persist until later in the division. The central cell in figure 88 shows a later prophase stage with the chromosome contraction in progress. The mirror-image effect is not clear, because the nuclei were not in the same focal plane. The endospheres are still intact, though one of them has drifted off into the cytoplasm after the dissolution of the ectosphere membrane. Metaphase figures are not easily recognized, because the spindle is not clearly shown with the Feulgen stain, but early anaphases are found without difficulty. If the ectosphere membrane is still intact, the spindle forms as a chord to it (fig. 98); but frequently it disappears before this stage, as in figure 99, where one of the endospheres has also disappeared, while the last remnant of the other is visible.

The direction of the spindles, relative to each other and to the cell, seems at first to be a matter of chance, both in the basal cell and in the spore mother-cell (fig. 92). This may be true until early telophase (fig. 100); but usually by this stage the spindles lie side by side, parallel to the long axis of the basal cell (fig. 89) and diagonally in the spore

mother-cell (fig. 93), where the intercalary cell is cut off somewhat to one side of the spore chain (fig. 101).

In late anaphase and early telophase we often see the effect (fig. 89, 92) that led Sappin-Trouffy to postulate a haploid chromosome number of two for the rusts. As the telophase progresses, the new endosphere is cut out (fig. 94) in the way described for the urediniospore, and the chromatin becomes distributed over its surface as in the top cell in figure 93. The pairs of nuclei resulting from the division of the basal cell both assume the expanded form; but of those resulting from the spore mother-cell division, only the spore nuclei become expanded, while most of the chromatin of the intercalary cell nuclei remains within the endosphere.

It is of interest to note (fig. 101) that the intercalary cells of a spore chain are generally cut off toward the same side. Possibly this has some function in the mechanism of spore discharge, but it seems more probable that it is connected in some way with the development of this unique method of spore production.

The spore nuclei are usually fully expanded by the time the spores are fully grown. The chromatin in the mature spore varies greatly in distinctness. Sometimes it is nearly all situated close to the ectosphere membrane and is not very evident, being, apparently, very finely dispersed. At other times it forms a distinct reticulum, but the heavy reticulum often obtained in haematoxylin preparations (fig. 103) is never duplicated with the Feulgen stain. This further indicates the misleading effects that may be obtained with dyes not truly specific for chromatin.

The germination of the aeciospores, including reversion of their nuclei to the unexpanded type, is identical with that already described for the urediniospores.

Here and there in the aecium of *Uromyces Fabae* one finds chains of columnar cells (fig. 102) with slightly expanded nuclei. No intercalary cells are formed in these chains, the cells remaining undivided after being cut off from the basal cells. These cells are thus the morphological equivalent of the spore mother-cells and of the peridial cells, the final division of which is also deleted. It should be noted that the basal cells from which these cells are cut off have the same type of nucleus. They may simply be an abnormality, but it is quite possible that they serve a purpose similar to the buffer cells in the uredinium and telium.

Finally, a few words should be said about the peridial cells, for they clearly illustrate the nuclear condition of the vegetative cells in general. They have nuclei that are actually slightly expanded, but this is not very apparent with some staining methods. To illustrate this point three lateral peridial cells of Uromyces Fabae are shown in figures 104, 105, and 106. Figure 104 was stained with haematoxylin and figure 106 with the Feulgen stain. It will be seen that the nuclei of both cells appear uniformly reticulate, no endosphere being discernible. Figure 105 was

stained by the buffer method. The endospheres are very distinct and are about 1.25  $\mu$  in diameter, while the nuclei of figures 104 and 106 are about 2.0  $\mu$  in diameter. The outer part of each nucleus in figure 105 is virtually invisible because of the almost complete absence in these cells of the ergastic material on which the staining method depends. The abnormally small amount of this material present in the endospheres accounts for their invisibility in the haematoxylin preparation. It will be noticed that a small granule, surrounded by a "heller Hof," is visible in the endospheres in figures 103 and 105. This may possibly be a true nucleolus.

Discussion.—The changes in nuclear form here described for the rusts are decidedly unusual, and both the mechanisms involved and the causes underlying the changes are in need of explanation. It is to be hoped that further study in this group and, particularly, in other groups of the higher fungi will make the complexity of the rust nucleus more comprehensible. In the meantime the existence of these changes must be faced, and we must interpret them as best we can.

We must first consider how the whole of the chromosome substance can pass through the endosphere membrane, apparently without this membrane becoming in any way disorganized. The passage of chromatin through a membrane was first postulated in Hertwig's (1902) chromidial hypothesis. Cowdry (1924) discussed this hypothesis fully, pointing out that the term chromatin has all too often been applied to any substance that shows an affinity for basic dyes; but he concluded: ". . . . we are obliged to admit that it is by no means a rare occurrence for nuclear material to pass into the cytoplasm in large or small amounts." In the rusts we have a refinement of this situation. The nuclear material passes not into undifferentiated cytoplasm, but into an outer nuclear sphere, the ectosphere, newly formed from the cytoplasm. Modern microdissection investigations help to explain the situation. As Dr. Robert Chambers pointed out to the writer several years ago in connection with a different problem, a cytoplasmic or nuclear membrane, if violently pierced, will rupture; but if a needle or other object is gently introduced, no damage is done, and the membrane reforms behind it as it is withdrawn. The membrane, after all, is not to be regarded as a solid structure, but rather as a layer of oriented molecules, perhaps of lecithin or some related substance, at a liquid-liquid interface.

The problem of the functional necessity for the development of two distinct nuclear types is really more important than the mechanism involved in the change. One striking feature is that the unexpanded nuclear form occurs at every point of the life-cycle where the nuclei must pass through a very small pore. These stages are: the quadrinucleate basidium, the nuclei of which pass through the narrow tip of the sterigma; the basidiospore, which infects by the formation of a slender thread passing into an epidermal cell; the intracellular hypha resulting from

basidiospore infection, the nuclei of which pass through a narrow pore into the intercellular space; haustorium formation, during which the nuclei enter the host cell through a narrow pore; the pycniospore, the nucleus of which passes into a receptive hypha; and finally the migrating pycniospore nucleus, which passes through the septal pores on its way to the primordium. It should further be noted that Pady's (1935b) illustrations of the persistent intracellular mycelium of Kunkelia nitens indicate what may be the same situation; the endosphere is evident only in the intercellular hyphae.

The only other points at which the nuclei are typically unexpanded are the brief interphase in the basidium, and the germination of the aeciospore and urediniospore. The germ-tubes of the aeciospores and urediniospores generally enter the host through the stomata, and their nuclei may divide several times before any haustoria are formed. The only recorded exception to this behavior is found in the aeciospores of Gymnoconia Peckiana. These were shown by Pady (1935a) to enter directly through the epidermal cells, but even here nuclear division usually preceded infection. The germ-pores of the aeciospores and urediniospores are always fairly large, and either type of nucleus can be formed, indifferently, after mitosis; the complicated process by which these nuclei discharge their endospheres does not, therefore, seem to have any advantage unless penetration of a host cell is to precede nuclear division. Then it would be functional, since apparently only the partly expanded nucleus, and not the fully expanded one, can revert to the unexpanded form by the method used in haustorium formation. Whether such a type of infection occurs in any exist-

ing species is doubtful.

In the fusion nucleus the prophase chromosomes attain such a length that the very large ectosphere might be essential here if these long chromosomes are necessary for the unrestricted formation of chiasmata. This, however, explains the very similar expansion in the aeciospores and urediniospores, and in the basal cells and spore mother-cells of all three stages, only if one assumes the evolution of all three types of sorus from a simple telium in which the spores were formed directly from hyphal cells without the intercalation of basal cells and spore mothercells.

Mechanical advantage may, conceivably, not be the sole explanation of the change in form of the nuclei. It will be noted that the expanded nucleus is found in those spores that must make extensive growth before renewing nutritive contact with the host. Acciospores and urediniospores frequently produce germ-tubes exceeding  $500~\mu$  in length, and their nuclei may divide several times before a host cell is entered. It is not known to what extent the germinating teliospore is dependent on the thallus to which it commonly remains attached. It appears from the work of Dietel (1915) that the water needed for germination is absorbed through the pedicel; but when the host tissue dies in the fall and the

spore does not germinate till the following spring, it seems likely that all the food needed for the production of the basidium and spores is stored within the teliospore. Possibly the reserve nuclear material is largely stored within the nucleus. In sharp contrast to these spores are the basidiospore and pycniospore, which have unexpanded nuclei and also make little or no independent growth. The basidiospore puts out a short beak before passing directly into a host cell, and the pycniospore nucleus migrates into a receptive hypha of the thallus without any true growth occurring.

Even if food storage has no bearing upon nuclear structure, it certainly affects the staining reactions of the nuclei. A study of the staining reactions suggests a well-ordered economy in the protein metabolism of these highly specialized parasites. It has been observed, by using a number of staining methods, that there is a strong tendency for the rust nucleus to stain like the host nucleolus and for the rust cytoplasm to stain like the reticulum of the host nucleus. A lack of the necessary enzymes for the elaboration of proteins from simpler substances may partly explain the obligate parasitism of the rusts. These staining reactions, coupled with the close association of the haustorium with the host nucleus observed by most students of the group, suggest that the host enzymes may serve to break down the host proteins into amino-acids and that these, after absorption by the haustorium, are once more elaborated into proteins with the aid of the host's own enzymes. It is not to be assumed that the resulting proteins would be identical with those of the host, since it is well known that a slightly altered environment will materially affect the products of enzyme activity. It has been observed that both the nucleoprotein and the other stainable proteins of the nucleus appear, from the staining reactions, to be greatly diminished in the invaded areas of a rusted leaf.

It has already been stated that the nuclei of the basidiospores and pycniospores are scarcely distinguishable with the buffer stain, while those of the thallus and the other spore stages stain strongly. The unusual phenomenon of the nucleus taking an acid dye in preference to a basic one is explained by the fact that it is ergastic material, probably mainly proteins related to those found in the host nucleolus, that is stained rather than nucleoprotein. By checking with the Feulgen stain it can be seen that much of the nuclear substance stained with haematoxylin is also not nucleoprotein, and this is probably the same material. The basidiospore and pycniospore, as already pointed out, need little reserve material, and this accounts for their poor stainability. It is significant that the staining reactions of the ostiolar hyphae suggest that they contain more of this material than do the vegetative hyphae. This is evidently an economy on the part of the fungus, since any ergastic material in the hyphae can be retrieved for use elsewhere in the thallus, but most of that in the pycniospores must be lost because very few of them succeed in performing their function.

It is further to be remarked that the staining reactions show that much of the ergastic material in cells that have performed their function or that have only a mechanical function, such as the peridial cells, is removed for use in the more active cells.

Unfortunately very little detailed information is available on nuclear structure in the other groups of the higher fungi. A study of the published figures suggests that, with the exception of the fusion nucleus, the nuclei of the Hymenomycetes correspond to the unexpanded type of nucleus in the rusts. The writer has been fortunate in having the opportunity to examine many of Dr. Alexander H. Smith's preparations of various species of Mycena. It is evident that in this genus the paired nuclei in the young basidium are of the unexpanded type, that expansion starts just before or just after nuclear fusion, and that the expansion is a process of vacuolization essentially similar to that seen in the rusts.

The extensive cytological studies of the Ascomycetes have been directed along lines very different from those followed in the present investigation, and interpretation of the nuclear structure is generally impossible. Two recent papers, however, suggest points of interest. DeLameter (1937) shows the hyphal nucleus of Eidamella spinosa as a dark sphere about 1.5  $\mu$  in diameter, in a hyaline zone about 2.0  $\mu$  in diameter. This strongly suggests a similarity to the slightly expanded nucleus commonly found in the more active rust hyphae. His division figures indicate that division starts within this inner sphere rather than beside it in the outer cavity.

Colson (1938), in an extensive study of Phyllactinia corylea, maintains that the binucleate condition of the oogonium arises by division of the oogonium nucleus rather than by the entrance of the antheridial nucleus. It is difficult to secure an exact picture of these nuclei from her somewhat conventional figures, but one nucleus is large and has a large inner body; the other is much smaller and bears some resemblance to the unexpanded rust nucleus. A comparison of Colson's text figure 7 with the writer's figure 85 will emphasize this similarity. A point stressed by Colson was that the proportion of ascogenous cells that formed asci was so high as to preclude the possibility of nuclear migration and the existence of an irregular dikaryon; for the divisions in the ascogenous hyphae were not conjugate. By "conjugate" Colson evidently meant side by side rather than simultaneous. If, however, the divisions occur simultaneously but end to end as in the dikaryon hyphae of the rusts and if the nuclei subsequently slide past one another, the high proportion of compatible pairs could be obtained.

The mechanism by which the nuclei of the dikaryon cells maintain their relationship as pairs has always been a matter of interest. The mirror-image effect seen at prophase in the aeciospore basal cells clearly indicates the existence of two opposed and balancing forces. The mutual repulsion might well be due to similar charges on the two nuclei. Certainly it must be a force that will be increased as the nuclei are brought closer together; otherwise a balance could not be effected. It must also be due to some quality shared by all nuclei rather than to a difference between the nuclei of opposite strains; otherwise the balance seen in the occasional trinucleate cells could not be maintained. The mirror effect seen in figure 88 indicates that one of the forces acts upon a particular point in each chromosome. If the repulsive effect is due to equal charge, it is necessary only to assume that the charge is reduced at the time of fusion, rather than reversed, for the force of attraction will still be active. The occurrence of trinucleate cells is of additional interest, since it indicates that, even though the nuclei of a haploid thallus are alike in strain, there may be a difference in potency between sister nuclei. This may account for occasional findings that seem to represent the migration of a nucleus from a dikaryon cell to a monokaryon.

The present observations seem to strengthen the view that the process of diploidization should be regarded as essentially similar to the process in the Hymenomycetes. The attempt to identify the structures involved as male and female organs leads to

serious difficulties.

Lamb (1935) pointed out that, according to the view that the receptive hyphae are trichogynes leading to egg-cells, diploidization by the fusion of hyphae from intermingling monokaryon mycelia is fertilization of one female element by another. Ashworth (1935b), discussing the stomatal hyphae accompanying the pycnia of Endophyllum Sempervivi, pointed out that connections could be traced between these hyphae and others leading to haustoria, whereas a trichogyne would be expected to connect only with a reproductive structure. The same investigator (1935a) described the occurrence of stomatal hyphae in different stages of several rusts. The finding of such hyphae accompanying the uredinia of Uromyces Fabae strengthens Ashworth's contention that they must not be regarded as specialized female structures, although it is possible that they occasionally serve as receptive hyphae.

In the species examined it seems certain that the ostiolar hyphae of the pycnium are the main, if not the only, places of entry for the pycniospore nuclei. This militates against the view that the pycnium is

strictly a spermogonium.

It is evident that few introduced nuclei reach a primordium and that its diploidization is completed by these few dividing repeatedly to supply the required number. This fact and others gleaned from a study of the partly diploidized accium show the behavior of the pycniospore nuclei to be very different from that of the nuclei of true spermatia, which do not divide repeatedly during their migration to the egg. They do not divide, after entering the egg, to supply spermatia for adjacent eggs; nor do we expect to find eggs arranged in rows, so that the spermatia have to pass through one in order to reach another. Finally, it is seen that the difference in size and form between the nuclei of the thallus and the

introduced nuclei is not one of sex: if this were so, the nuclei of the basidiospores and haustoria would be male, and those of the aeciospores and uredinio-

spores female.

When the differences in mode of life of the Hymenomycetes and the rusts are considered, it is no longer surprising that their diploidization processes should have developed along somewhat different lines. It must be remembered that the rust thallus soon virtually exhausts the available food material in the invaded part of the leaf or stem. This condition would impose a serious handicap upon the pycniospore if it had to grow through the leaf to the primordium. Lacking large quantities of reserve material, the pycniospore would have to establish connection immediately with the host or with the thallus. If the host cells are already exhausted, the logical solution of the difficulty is for receptive hyphae to be formed so that the pycniospore nucleus can enter the thallus without penetrating the host at all. The production of nectar in the pycnia for the attraction of insects that will distribute the spores entails the production of receptive hyphae where the insects will deposit these spores-namely, in other

Bacteria and fungi cannot normally grow in the nectar. (That they do occasionally grow in diluted nectar if the weather is very moist may explain some reports of pycniospore germ-tubes growing down through the ostiole.) As Dr. A. H. R. Buller pointed out to the writer some time ago during a discussion of this subject, quite apart from the need of preventing mold growth in the nectar it is necessary that the pycniospores should be unable to grow in the nectar of their own pycnia. What could be more natural than that, having developed a method of entering the thallus without germinating, they should in time lose their power of germination? Parenthetically it may be suggested that some of the cases of slight germination reported for these spores may actually be merely the effect often seen when bacteria are placed in strongly hypotonic solutions: the protoplast swells to such an extent that it bulges out through the weakest part of the wall.

The invading nuclei do not diploidize the cells through which they pass. As Lamb pointed out, to do so would be waste of nuclear substance; for the future growth is localized in the aecium, and the remainder of the thallus serves only to conduct nu-

trient material to it.

The acceptance of the view here expressed necessitates the use of the terms "pycnium" and "pycniospore" in preference to "spermogonium" and "spermatium." It is unfortunate that Lamb, who strongly championed the same view, should have obscured his argument by clinging to the latter terms.

## SUMMARY

By the use of new staining methods to supplement the usual procedures it has been shown that there are two distinct types of nucleus in the rusts, and the transition from one to the other has been elucidated. What is termed the unexpanded form is adopted in every part of the life-cycle where migration of the nucleus through a narrow pore is necessary. In the transformation of the unexpanded nucleus into the expanded, a new nuclear sphere, the ectosphere, is formed about the original nucleus. The chromatin passes through the original nuclear membrane and becomes distributed through the ectosphere, leaving the original nuclear sphere, or endosphere, completely devoid of it. The endosphere is the body commonly referred to by rust investigators as the nucleolus, but the use of this term is to be deprecated, since it is not homologous with the nucleolus of the higher plants. What is possibly a true nucleolus may sometimes be discerned within it.

The expanded nucleus is found in the aeciospores, urediniospores, and teliospores, and in their basal cells and spore mother-cells. This suggests the possibility of a common origin for these three spore forms.

With the aid of the Feulgen method, nuclear division has been followed in greater detail than was

previously possible. In the unexpanded nucleus the spindle forms equatorially in the single nuclear sphere. In the expanded nucleus it forms beside the endosphere as a chord to the ectosphere membrane.

The nuclei of the mycelium usually have some of their chromatin outside the endosphere, but their division is essentially similar to that of the unexpanded nuclei.

Evidence has been secured that, in *Puccinia Sorghi* and *Uromyces Fabae* at least, the pycniospore nuclei enter the thallus through the ostiolar hyphae of the pycnium and that very few of these nuclei enter each primordium. Complete diploidization is accomplished by their repeated division after the primordium has been reached.

Preservation of the dikaryon condition by the operation of two opposed, balancing forces is indicated by the observation that in prophase the conjugate nuclei in the accium tend to appear as mirror images of each other.

# A DEVELOPMENTAL ANALYSIS OF HETEROSIS IN LYCOPERSICON I. THE RELATION OF GROWTH RATE TO HETEROSIS 1

# William Gordon Whaley

Observations on the occurrence of hybrid vigor were a part of the first studies of plant hybridization. Kölreuter (1766), Knight (1799), Sagaret (1826), and Gärtner (1849), among the early investigators, recorded instances of great increases in size and yield in the progeny of certain crosses. Mendel (1865) reported that progeny secured in crossing two types of Pisum usually exceeded either parent strain in stem length and showed greater luxuriance generally. Nearly all the early papers Received for publication April 24, 1939.

The writer wishes especially to express his appreciation to Professor E. W. Sinnott under whose direction this investigation was conducted. He is also indebted to the members of the Department of Botany of Cornell University and to Professor R. A. Emerson for the use of laboratory and field facilities in the summer of 1938 and for much helpful criticism, and to Professors Eric Ashby and E. W. Lindstrom for their kindness in supplying seed

The second paper in this series will appear in a later issue of the American Journal of Botany.

contain references to occurrence of greater vigor in the progeny of crosses, but no attempt was made to explain the phenomenon until many years later when Jost (1907), largely on the basis of Darwin's (1875, 1877) observations, suggested that the more vigorous growth of hybrids has as its cause the same stimulus which enables the egg to develop.

It was, however, some time after the discovery of Mendel's paper before attention was focused upon the immediate effects of cross-breeding. An understanding of Mendelian principles of inheritance resulted in several attempts to explain the cause of in-

creased vigor in hybrid plants.

G. H. Shull (1908, 1909, 1910) and East (1908, 1909), working independently with maize, established the main facts upon which the first explanations were based. Both observed that self-fertilization in maize led to a decrease in size and vigor, the decrease becoming less and less in each generation until eventually a point was reached beyond which (presumably) no further loss of vigor took place. They noted further that progeny derived from crossing inbred lines usually excelled the parental types and that the yield per acre from the  $F_1$  generation was always greater than that from the  $F_2$  generation. After observing a large number of crosses, Shull (1910) suggested that vigor of hybrids is a direct result of hybridization and that the degree of vigor is directly dependent upon the number of heterozygous factors present.

Keeble and Pellew (1910) reported a cross between two half-dwarf varieties of Pisum which produced a hybrid greatly exceeding either parent in vigor. They noted that one of the parents was characterized by long internodes and thin stems and the other by short internodes and thick stems. On the basis of the F2 distribution they assumed one parent to have the genetic constitution tL and the other Tl, these being factors controlling stem diameter and internode length, respectively. The hybrid, of course, has the genetic constitution TtLl, and the authors ascribed the increased vigor to the presence of both of these factors. In the same year Bruce (1910) published a mathematical interpretation supporting the idea of combination of simple dominants as the cause of hybrid vigor.

In 1912 East and Hayes published the first paper devoted exclusively to the phenomenon of hybrid vigor. The authors reviewed G. H. Shull's data (1908, 1910, 1911) and their own previous work (East, 1908, 1909; Hayes and East, 1911). Both Shull and East and Hayes noticed that the degree of increase in vigor secured from a particular cross varied directly, at least in most cases, with the degree of heterozygosity which the cross produced. Since the increase in vigor is associated with hybridity, and hence with heterozygosity, and as the degree of increase appears to depend directly upon the degree of heterozygosity possessed by the hybrid, they assumed that heterozygosity itself is the immediate cause of hybrid vigor.

In 1914 G. H. Shull restated this hypothesis. He pointed out, however, that while the degree of hybrid vigor present seems to depend, within limits, upon the genetic dissimilarity exhibited by the parents, the combination of different Mendelian genes may be only one factor concerned. There remains also the possibility of the effect of the elements of the male nucleus upon the egg-cytoplasm, as pointed out by A. F. Shull (1912a, 1912b). For the purpose of avoiding the implication that all the genetic differences responsible for the stimulation of physiological processes in hybrids result from gene action, Shull proposed the term "heterosis" as a substitute for the phrases "stimulus of heterozygosis," "heterozygotic stimulation," "stimulating effects of hybridity," and other terms previously used to denote the condition bringing about increased vigor in hybrids.

Castle (1916) made a study of the growth of guinea pig hybrids and their parents and found evidences of hybrid vigor. He drew a distinction between the direct effects of inherited characters upon the size of the offspring and the effect that a combination of different gametes has upon size through increasing metabolic activity and supposed that a chemical difference between gametes caused the added vigor.

In 1918 Jones proposed a new explanation for heterosis by assuming the action of linked, dominant genes. Jones' hypothesis rests upon a series of assumptions: first, that there are many genes concerned in the development of any of the important characters of an organism; second, that these genes belong to various linkage groups; and third, that the genes concerned with the development of greater size are, at least partially, dominant.

There is much evidence to support the first and second of these assumptions. Many genes must be involved in the complex processes which are part of development, and if a large number are concerned, they must be located on at least several if not all of the chromosomes. The third assumption, however, that genes concerned with the development of greater size are usually dominant over those for lesser size lacks proof. Most hybrids are intermediate with respect to commonly observed size characters, and rarely does there seem to be any dominance of large size. Without at least some degree of dominance, however, there would be no cumulative size effect in the heterozygous condition, and Jones' explanation would not hold.

Collins (1921) proposed another hypothesis which does not require the assumption of dominance. From observation of the effects of inbreeding in maize, he believed that the loss of vigor which it produces is due not to the elimination of dominant, favorable factors but to the appearance, in homozygous form, of deleterious recessives. Conversely, the increased vigor which so often attends hybridity Collins attributed to the suppression of these deleterious recessives.

Comparatively little attention was paid to the physiological basis of heterosis until the experiments of Ashby (1930, 1932, 1937) with maize and tomato hybrids. Ashby's conclusions may be summarized as follows: first, heterotic hybrids do not differ from their more vigorous parent as to cell size, growth rate, respiration rate, photosynthetic efficiency of the leaves, or time of flattening off of the sigmoid growth curve; second, the hybrids observed seem to inherit growth rates as dominant Mendelian characters; third, the hybrids have a greater initial embryo weight than the parental types. He assumes that if a hybrid does not grow more rapidly than its parents, and does not grow for a longer period of time, and yet is finally larger than the parents, it must have started with a size advantage. Since these conditions seemed to obtain in the material which Ashby observed, he postulated that hybrid vigor is due simply to the possession by the hybrid of a bigger embryo-more "original capital." The hybrid thus has an initial advantage which is maintained throughout the whole period of growth. Its larger embryo is in turn due to some very early developmental difference, either in rate or duration of growth. Luckwill (1937) has confirmed Ashby's results for tomatoes, working particularly with the later growth phases. He also made some sections through young shoot primordia in the seed and concluded that those of the F<sub>1</sub> plants are larger than those of the parents. Luckwill's results will be discussed in detail later in the second paper of this series.

Ashby's hypothesis has been attacked by several investigators. Sprague (1936) performed experiments with maize similar to those made by Ashby and obtained different results. He found that in the early (post-embryonic) growth stages the hybrids grew faster than the parents. Actually his results do not necessarily conflict with those obtained by Ashby, because they deal primarily with different parts of the growth curve. Ashby was concerned mainly with the grand period of growth, after the seedling stage, whereas the differences in rates which Sprague found were confined to the very early seedling stage.

Lindstrom (1935) attempted to test Ashby's hypothesis by cutting back growing hybrid seedlings. In this manner he sought to reduce the meristematic capital of the hybrids to the same, or a lesser, amount than that of the parents. In every case the hybrids finally exceeded the parents in both plant weight and yield. The growing tissue which Lindstrom removed, however, is not comparable to the "original meristematic capital" to which Ashby refers the phenomenon of heterosis.

East (1936) took Ashby to task both for his observations on the expression of heterosis and his theoretical deductions and then proposed a new explanation. He assumed that dominance is absent in size traits, but that genes controlling them occur in numerous series of multiple alleles. If in a given series each member affects a different physiological process, then the heterozygous condition may be expected to produce cumulative effects. That is, if a1 affects a somewhat different process than its allele a2, a1 a2 may have a greater effect than a1 a1 or a2 a2. This hypothesis implies that there is complementary action between different mutations at the same locus —that is, a<sub>1</sub> supplies what is lacking in a<sub>2</sub>, or vice versa. There is little experimental evidence, however, to support this idea of complementary action between alleles.

Until the publication of Ashby's papers dealing with the observation of physiological differences between inbred and crossed lines of maize and tomatoes the problem of heterosis was approached almost solely from the point of view of theoretical genetics. The effects of heterosis have been observed for the most part in mature plant characters, and interpretations have been concerned mainly with quantitative differences between hybrid and parental types. Little has been found as to the underlying manifestations of heterosis, and genetic interpretation has therefore been difficult. Ashby emphasizes, quite properly, that the causes of hybrid vigor must ulti-

mately be physiological in nature. The problem is a developmental one, and any understanding of it requires first a knowledge of the developmental differences concerned.

The present study deals with a series of experiments designed to determine the character and developmental basis of some of these fundamental differences. The problem has been approached through a comparative study of the development of inbred and hybrid plants, with particular reference to the rôle of the apical meristem. It was thought desirable to study this meristem in some detail, both because of Ashby's contention that the "original meristematic capital" is the principal factor concerned in heterosis and because the apical meristem, as the functional embryo of the aerial parts of the plant, is the seat of origin of morphological differences observable in mature plants and their organs.

MATERIALS.—Two different tomato hybrids and their parents were used as experimental material. For the sake of brevity, the types will be described in detail and thereafter referred to by designated symbols.

Cross I.—Race A of this study was Lycopersicon esculentum, Line 1755-7, secured from Professor E. W. Lindstrom. This variety is a dwarf type. The plants are relatively slow growing, rarely attaining a height of more than two feet. A heavy pubescence covers all the vegetative parts. The fruits, which are borne in a few dense clusters near the apex of the plant, are pear-shaped and yellow in color. Fruits, flowers, and leaves are all of medium size. The line is homozygous for the genes d, p, o, s, r, y (MacArthur, 1931).

Race B was Lycopersicon pimpinellifolium, Line 1748-5 (Lindstrom), a race of the "currant" tomato. The plants have long slender stems. Stems, leaves, flowers, and fruits are all small in comparison to the other species used. Many fruits are produced, but the number of seeds per fruit is small.

Hybrid A  $\times$  B [1755-7 (female)  $\times$  1748-5 (male)] was the hybrid from which most of the data were collected. A detailed description of this plant will be given later.

Hybrid B × A was not obtained in large enough numbers for experimental use, because the small size of the flowers of plant B made hybridization difficult and only a few seeds were produced in each fruit. Observation proved, however, that it does not differ from its reciprocal.

Cross II.—Race C was Lycopersicon esculentum var. "Chinaman." The seed were obtained from Professor Eric Ashby, who states that this variety has been cultivated by Chinese gardeners in Australia since about 1860. The line is homozygous for several recessive genes, including br, brachitic stem with shortened internodes; f, fasciated fruit; and wt, a gene producing a curious inrolling of the leaf margins. The plants rarely reach a height of two feet.

Race D was Lycopersicon racemigerum, a South American species which is homozygous for the genes D, P, O, R, S, Y of L. esculentum, or homologous

a Immature fruits counted to determine total.

b Standard error.

genes. These seed were also secured from Professor Ashby. The plants grow ten feet or more in height when staked. The fruits, borne in large trusses, are about the size of gooseberries. The species is selffertile and is somewhat difficult to cross. These C and D races have been used by both Ashby (1937) and Luckwill (1937) for studies of hybrid vigor.

Hybrid C  $\times$  D [ $\dot{L}$ . esculentum var. "Chinaman" (female)  $\times$   $\dot{L}$ . racemigerum (male)] has been used for most of the observations. Its characters will be discussed in detail later.

Hybrid D $\times$ C, the reciprocal cross, was observed for some characters and found to be essentially the same as the hybrid C $\times$ D. It differs somewhat in seed size, and consequently minor differences are observable in the level of the growth curves during the early stages.

Hybrid seeds of these crosses were first obtained from Professors Lindstrom and Ashby, but each of the crosses has been repeated many times by the writer

Large numbers of plants of the parents and progeny of each cross were grown in the field for two summers, first in Amherst, Massachusetts, during the summer of 1937, and then in Ithaca, New York, during the summer of 1938. Plants were also grown in the greenhouse of Columbia University during two winters. The same results were obtained in each of the four seasons, so only those plants grown during the summer of 1938 at Cornell University will be discussed.

The life cycle of the plants was divided for study into three purely arbitrary stages: (1) the germination period; (2) the first eight weeks of growth; (3) the eighth to sixteenth weeks of growth. This division was made necessary by the writer's inability to make observations during sixteen consecutive weeks of field growth. The germination and very early seedling growth periods are treated separately because the plants were grown under different conditions.

For convenience the report on this investigation has been divided into two parts—the first dealing with a study of growth rates and size differences as related to heterosis, the second with the rôle of the apical meristem in heterosis. The second part will be reported in a paper to follow this one.

CHARACTERS AFFECTED BY HETEROSIS.—A knowledge of the characters concerned in the expression of hybrid vigor is essential to an understanding of heterosis. Table 1 presents a comparison of some of the more readily observable quantitative characters of parents and hybrids of the two crosses.

Height.—In both crosses height of the hybrid exceeds that of the taller parent. Height, however, is not a good criterion in this instance because in each case one of the parents is a dwarf type. Further, the number of lateral branches developed has a marked effect upon height in tomato plants as does the time at which flowering begins and many other factors. Tall-dwarf crosses were purposely selected for study because their use makes it possible to determine whether meristem size is related to heterosis or the action of the Dd gene.

Leaf size.—Leaf size in tomatoes is difficult to measure. It is even more complex in the present instance because of the possession by one of the types of peculiarly rolled leaflets. No attempt has been made to determine areas, but leaf length has been recorded, together with the length of the second basal leaflet. These measurements afford a rough approximation of leaf size. Generally, the hybrid leaves are intermediate in size between those of the parents, but they tend to be farther above the mean of the parents than do the other determinate organs measured. Occasionally the leaves are larger than those of the larger leaved parent.

Flower size.—Size of the flowers in the hybrids observed is intermediate between those of the parents. This condition is illustrated by corolla width measurements given in table 1. Heterosis does not affect size of the flowers but rather the number produced.

Cell size.—Cell size was measured in each of the types, using parenchyma cells in the petioles of mature leaves. The values are given in table 1 and indicate that the hybrid does not have significantly

larger cells in either cross.

Fruit.—Yield, to be considered in relation to heterosis, must be analyzed into its two components, fruit size and fruit number. The effect of heterosis in increasing yield, as may be seen in table 1, is one of increasing the number of fruits per plant. Individual fruit weights in the hybrid are intermediate between those of the parents. As a result, increased fruit number is necessary in the hybrid before it can equal the yield of the larger fruited parent, and a great increase is essential to raise the yield materially. In both crosses the yield of the hybrid is greater than that of either parent.

Weight.—As indicated in table 1, the fresh weight of the vigorous hybrids exceeds that of the larger parent in each case. Fresh weight was used as a measure of growth and an indication of heterosis throughout the experiments, first because it probably is the best measure of plant volume, with which heterosis seems to be primarily concerned, and second, because it is the only measure equally well adapted to both germination and early growth and to later stages where measurement is complicated by the pro-

duction of fruit.

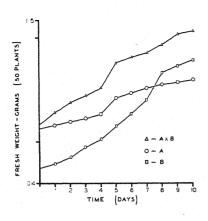

Facilities for making large scale dry weight determinations were not available, hence dry weights were determined only at intervals to furnish checks upon other measurements. The figures given in table 1 are average weights of plants air-dried for 14 days. The hybrid weight in each instance is greater.

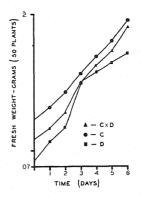

These results are in general agreement with what has been observed by other investigators. East (1936) noted that the effects secured from heterosis are very like those which might be obtained by adding fertilizers to the soil. This is certainly true in the present experiment. "Hybrid vigor" appears to be concerned only with total plant size. It seems to have little or no effect upon the determinate organs. Flowers, fruits, and even seeds are such organs, and they are not materially affected. Upon the leaves, however, there is some effect. It will be shown later that this is probably the result of the influence of heterosis in raising the general metabolic rate of the plant rather than its influence upon the size of the meristems or the leaf primordia. Flowers and fruits are end products. The leaf, on the other hand, is the primary metabolic organ of the plant. Hence, any change in the level of physiological activity might reasonably be expected to have an effect upon its size.

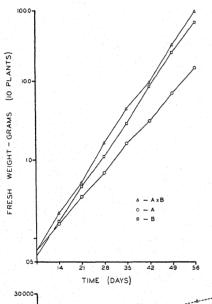

The relation of growth rate to heterosis.— Cross I (A, B, and A  $\times$  B).—Comparative growth rates during and immediately after germination were determined in the following manner: five hundred seeds of each type were selected individually so as to exclude waste material and injured seeds, and weighed. Seeds were soaked in water for four hours and placed on moist filter paper in damp chambers. They were arranged in alternate sectors on the paper, fifty seeds to a sector, six sectors to a dish. The seeds were about 8 mm. apart. The moist chambers were kept in an incubator at 28.5°C. At twentyfour hour intervals fifty seeds of each type were removed, dried lightly with soft absorbent paper, and weighed. Figure 1 shows the fresh weights of fifty plants, plotted on a log scale against time in days. The entry at zero time is the weight of fifty dry seeds. The first day includes the four hour soaking period. The first part of the curve undoubtedly represents only water absorption. Even in this period the hybrid and one parent (B) differ considerably from the other parent. The types seem to vary somewhat in the time when the initial marked increase in weight takes place. Germination in the hybrid is observable a few hours earlier than in either parent. The most significant point is the difference in order of the types in size at the end of the eighth day. The hybrid is still heavier, but the parent races have changed position, B having passed A. In view of the great difference between the seed weights of the two types, this result does not support the idea that the initial embryo size has an influence on growth, either as to rate or relative level. It is important that the general slope of the hybrid curve is essentially parallel to that of the faster-growing parent (B), but at a considerably higher level. What appears to be a decline in rate of growth during the later days represented in these curves is probably due solely to a reduction in food supply, since nothing except water was added to the cultures. This experiment was repeated four times with each set of materials, and the same results were obtained in each instance.

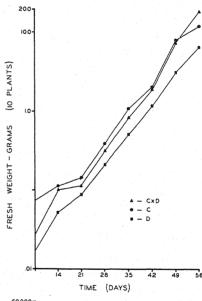

Growth during the second period, covering the first to eighth weeks, is shown in figure 2. Values given are total weights of ten plants in grams. The material used for this part of the experiment was planted in the greenhouse on July 1 and sampled at weekly intervals thereafter, being kept in the greenhouse during the whole eight weeks. The interchange of position by the parent types takes place a few days later in soil-grown plants than in seedlings grown in moist chambers. This condition is probably to be expected because of the more rapid early growth of the latter. The period of time represented in figure 2 covers the major part of the grand period of growth, after germination and before the setting of fruit. The results are in agreement with those of Ashby (1932, 1937) and Luckwill (1937) in that the hybrid has essentially the same growth rate as the faster-growing parent but is at a somewhat higher level.

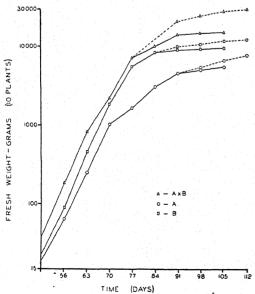

Figure 3 shows the fresh weight increase during the third period from the eighth to the sixteenth weeks. The plants represented here were planted in the greenhouse May 1, moved into the field June 20, and sampled weekly from the eighth to the sixteenth weeks after planting. Hence, while the plants of the second and third parts represent supplementary growth periods, and while all plants in each set were handled under uniform conditions, figure 3 must not

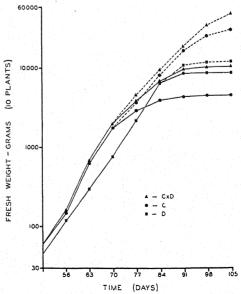

be considered as simply an extension of figure 2, because of the difference in environment. This does not, however, invalidate the results for comparative purposes. Fifty plants were weighed in the first five samples. As the plants increased in size it became impossible to handle such large numbers rapidly enough to prevent loss of weight by wilting, even though all sampling was done before sunrise. For this reason the number of plants was progressively reduced to forty, thirty, twenty, and finally ten in the last two sampling periods. In order that weights be comparable, the final figures have all been calculated on the basis of total weight of ten plants. The solid lines in figure 3 represent fresh weight of the vegetative parts of the plant; the dotted lines, plant weight plus fruit weight. Both sets of data show that the hybrid and its faster-growing parent (B) have about the same rate of increase. At approximately the seventy-seventh day the curves of the hybrid and parent B begin to level off, that of the parent a little faster than that of the hybrid. Growth begins to slacken in the smaller parent (A) about a week before it does in the larger parent and the hybrid. The curves indicate that the growth of parent A is very different from that of either B or A X B. Its fruits mature later, and for this reason had it been possible to grow the plants for a few more weeks, they might have produced more fruit; but since ripening was well advanced, it is probable that no significant increase would have resulted. Although the curves of both the hybrid and its faster-growing parent begin to level off at about the same time, that of the hybrid falls off less rapidly, and hence the difference between hybrid and parent is greater in the end than at any time during development.

"Hybrid vigor" in this particular cross is the result of three conditions: First, the hybrid has an initial advantage in that the seeds are larger. As will be shown later, this situation does not obtain in the other cross. Second, the hybrid gains more during the very early stages of growth, partly as a result of earlier germination and partly because it grows more rapidly. Thus the hybrid obtains an early advantage. As its growth rate during the grand period of growth is essentially the same as that of the faster-growing parent, this advantage is maintained. Third, the hybrid grows more than its parents during the final stages of growth. As a result, the initial advantage which the hybrid gained by faster early growth is markedly increased during the fruiting period, giving final differences greater than those at any time during growth.

Cross II.—The cross between L. esculentum var. "Chinaman" and L. racemigerum presents a somewhat different situation. The seed weight of the hybrid, the entry at zero time on figure 4, is intermedi-

ate between those of the two parents. If seed size of the hybrid is intermediate, presumably its embryo size is also. Luckwill (1937), however, reported that the initial dry weight of hybrid seeds in the reciprocal of this cross is significantly greater than that of either parent. The seeds of parent D begin to germinate slightly before the hybrid seeds.

Because of their larger size it was impossible to grow these plants in culture chambers as long as the plants in cross I. At the end of the sixth day, however, the seedlings occupy the same respective positions as to weight as did the seeds.

Figure 5 shows that while the hybrid growth curve is similar to that of parent C, during the grand period of growth it actually grows somewhat faster, since, after having started with a disadvantage in size, it exceeds the C parent in weight after about the seventh week. The entries in figure 6 indicate that here, also, the hybrid began to exceed the parent at about the same time. The change in slope of the curves between the 14th and 21st days in figure 5 is probably the result of retardation brought about by transplanting the seedlings.

Figure 6 shows the similarity between the growth curves of the hybrid and parent C, up to the time of fruit production. As in the previous cross, the curves begin to flatten off at about the same time. Here, also, the hybrid increases its advantage during the later stages. The increased advantage is more noticeable in the weight of the vegetative parts alone in this case, primarily because the hybrid had not completed fruit production at the conclusion of the experiment. The second parent, D, is of interest because it increases in weight much more slowly, but grows considerably longer than either of the other types, finally attaining an intermediate position with respect to plant weight. Its fruit yield is relatively low, perhaps because fruiting begins later.

Hybrid vigor in this cross, as in the first, is due to an early period of faster growth and to more active later growth in the hybrid. In this instance this faster growth is not so noticeable in the very early seedling stages but is seen mainly early in the grand period of growth. The hybrid starts out smaller than one parent in seed size, overtakes its larger parent at about the seventh week of growth, and gains an advantage which it again increases just before maturity. The amount of heterosis is less pronounced in the progeny from this cross than in the previous case, but it is clearly evident.

### SUMMARY

A study was made of growth rates of the parents and hybrids in two *Lycopersicon* species crosses showing heterosis.

Fig. 1-6.—Fig. 1 (above, left). Cross I. Increase in fresh weight following planting on moist filter paper. Cultures kept in the dark at 28.5°C.—Fig. 2 (center, left). Cross I. Increase in fresh weight for 56 days after planting. Plants grown in greenhouse.—Fig. 3 (below, left). Cross I. Increase in fresh weight from 49th to 105th days after planting. Plants grown in the field. Solid lines represent weight of vegetative parts; dotted lines, vegetative parts plus fruit.—Fig. 4 (above, right). Cross II. Same as fig. 1.—Fig. 5 (center, right). Cross II. Same as fig. 2.—Fig. 6 (below, right). Cross II. Same as fig. 3.

Heterosis, in the crosses observed, produces its effects by an influence on total plant size. The size of determinate organs is not increased by heterosis, but they are produced in greater numbers.

In both crosses the hybrid grows faster than either parent in the early post-embryonic stages and during the fruiting stages, but differences are much less marked during the grand period of growth.

The presence of heterosis is not always accompanied by the possession by the hybrid of a larger embryo.

# HETEROTHALLISM AND SEGREGATION OF SEXES IN ASCOBOLUS GEOPHILUS <sup>1</sup>

Edwin M. Betts and Samuel L. Meyer

KNOWLEDGE CONCERNING heterothallism and homothallism in the Ascomycetes is, as yet, incomplete. Members of the genus Ascobolus Pers. furnish excellent material for investigations into the sexuality of the group. Dodge (1920) described heterothallism in Ascobolus magnificus Dodge, and his initial observation on sex segregation in the genus was confirmed by Gwynne-Vaughan and Williamson (1932). Heterothallism in Ascobolus carbonarius Karst. was demonstrated by Betts (1926), and it was shown for the first time that of the eight spores in an ascus, four are of one sex and four are of the opposite sex. Green (1931) found Ascobolus stercorarius (Bull.) Schröt. to be heterothallic, an observation confirmed by Dowding (1931). Schweizer (1931) described a new species, Ascobolus strobilinus Schweizer, which proved to be homothallic. Betts and Meyer (1938a) obtained results which indicate that sex segregation in Ascobolus carbonarius Karst. is not due to chance distribution. A preliminary report was recently presented by the writers (Betts and Meyer, 1938b) concerning sexuality in Ascobolus geophilus Seaver.

The importance of the Ascomycetes as material for genetic research has been clearly demonstrated through the investigations of Dodge (1928, 1931, 1934, 1935, 1936), Lindegren (1932, 1936), Lindegren and Lindegren (1937, 1939), Lindegren and Rumann (1938), Campbell (1937), Seaver (1937), and Dodge and Seaver (1938) and lends impetus to further studies of sexuality in the group. The present contribution is an elaboration of the preliminary report previously mentioned (Betts and Meyer, 1938b).

MATERIALS AND METHODS.—Ascobolus geophilus was first reported by Seaver (1911) as the European species, Ascobolus viridis Curr. It was later recognized as a distinct species and was redescribed as Ascobolus geophilus (Seaver, 1916). Its distribution is given by Seaver (1928) as New York to Iowa and Colorado and Winnipeg, Canada. Recently, in obtaining cultures of Ascobolus carbonarius Karst. from soil (Betts, 1926) collected at Charlottesville, Virginia, a single apothecium of Ascobolus geophilus Seaver appeared. The discovery of the species at Charlottesville extends the range and gives the first report of its occurrence in the South.

Spores from this apothecium were sown on soil decoction agar in sterile Petri dishes (Betts, 1926). The spores germinated within an hour without heating, a condition not found in other species in the genus, all of which require relatively high temperatures to initiate germination. After the mycelia from germinated spores had covered the surface of the agar, they were transferred in small blocks to sterile soil in jelly glasses, the soil having been pre-

<sup>1</sup> Received for publication June 8, 1939.

viously moistened with distilled water. Within three to four weeks mature ascocarps had developed. From these ascocarps spores were obtained in sufficient numbers to make possible an examination of the sexual strains in the species.

Spores from asci of Ascobolus are shot out with considerable force. If glass slides are placed over the apothecia, they are soon covered with spores. By means of microdissection needles, single spores were removed from the slides and placed in separate Petri dishes for germination. The mycelia were allowed to grow until the agar in the Petri dishes had become completely covered, and then blocks of agar were transferred to jelly glasses, as previously described. Eighty-nine monospore cultures, the spores selected at random, were numbered 1 to 89 and grown in triplicate, a total of 267 cultures.

To test the spores for plus and minus strains, fifteen monospore cultures were selected at random, labeled 1 to 15, and grown in all possible combinations. One hundred twenty crosses were set up in triplicate, a total of 360 cultures.

To determine the sexual strains of spores within a single ascus, apothecia were teased apart in water by means of finely ground needles, the single ascus picked up with a capillary pipette, placed on a glass slide, and allowed to dry. The ascus wall adhered to the surface of the slide, and it was then possible to remove the spores in the order of their occurrence in the ascus with the microdissection apparatus. Each spore was placed in a separate Petri dish of soil decoction agar for germination and the dishes numbered 1, 2, 3, 4, 5, 6, 7, 8, corresponding to the posi-

<sup>&</sup>lt;sup>a</sup> The plus sign (+) is used to indicate the presence of apothecia resulting from the crossing of mycelia from individual spores; the minus sign (—) indicates that no apothecia were formed. Final observations were taken after a period of 30 days. A similar method of designation is used in tables 2 and 3.

tion of the spores in the ascus, spore 1 at the base and spore 8 at the apex. After germination, mycelia from the different spores were grown in all possible combinations.

A total of 706 cultures of Ascobolus geophilus was observed during the period of investigation.

DISCUSSION AND RESULTS.—None of the 89 monospore cultures produced ascocarps. This constitutes negative evidence proving that the species is not homothallic.

In table 1 are shown the results obtained when the mycelia from 15 spores, selected at random, were crossed in all possible combinations. Spores 1, 8, 10, and 12 are of one strain which may be arbitrarily termed the minus (-) strain. Spores 2, 3, 4, 5, 6, 7, 9, 11, 13, 14, and 15 are of the opposite or plus (+) strain. In no case were ascocarps formed when spores of the plus or minus strain were crossed with each other—that is, plus with plus or minus with minus. Apothecia appeared in all crosses involving mycelia from spores of opposite strain, as plus with minus or minus with plus. For example, spore 1 produced a mycelium from which no apothecia developed in crosses with the same mycelium or with the mycelium from spores 8, 10, and 12. On the other hand, when the mycelium which developed from spore I was crossed with that from any of the spores other than 8, 10, and 12, ascocarps were produced. Conversely, the mycelium from spore 2 produced no apothecia when crossed with itself or with the mycelium from spores 3, 4, 5, 6, 7, 9, 11, 13, 14, and 15. Ascocarps were developed when the mycelium from spore 2 was crossed with the mycelium from spores 1, 8, 10, and 12.

The observations presented in table 1 show that *Ascobolus geophilus* is heterothallic, since there are two sexual strains and no apothecia are produced unless both strains are present.

Five asci were used to determine the sexual strains of spores within a single ascus. The asci were designated A, B, C, D, and E. Table 2 and figure 1 give the results for ascus A.

TABLE 2.

			Spore number	
	1	2 :	3 4 5	6 7 8

 $(4 \text{ and } 5) \times 1 = (-)$ 

$$(4 \text{ and } 5) \times 8 = (+)$$

In ascus A, spores 1, 2, 3, 6, 7, and 8 were removed separately, while spores 4 and 5 could not be separated and were picked up together. After ger-

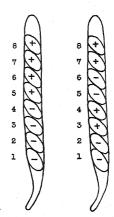

Fig. 1. Diagram illustrating segregation of sex factors in *Ascobolus geophilus* Seaver, ascus A (left), ascus B (right).

mination and growth, the mycelium from single spores was grown in all possible combinations. Spores 1, 2, and 3 proved to be of one strain, while spores 6, 7, and 8 were of the opposite strain. Spores 4 and 5 grown together failed to produce apothecia. This result was not expected from the arrangement of the other spores in the ascus and indicated that either the two spores were of the same strain or one had failed to germinate. Since three spores were of one strain and three of the opposite strain, it was obvious that spores 4 and 5 could not be of the same genetic constitution for sex. In order to determine which spore failed to germinate, the mycelium from spore 4 or 5, as yet undetermined, was grown with the mycelium from spore 1 and with the mycelium from spore 8. In combination with spore 1, no ascocarps were produced; in combination with spore 8, ascocarps developed. The evidence obtained indicated that spore 4 germinated, while spore 5 did not. Since in ascus A, as shown in table 2 and figure 1, spores 1, 2, 3, and 4 are of one strain and spores 5, 6, 7, and 8 of the opposite strain, sexual differentiation takes place at the first division of the zygote nucleus.

$$(6 \text{ and } 7) \times (6 \text{ and } 7) = (-)$$
  
 $(6 \text{ and } 7) \times 2 = (+)$ 

The results are shown for ascus B in table 3 and figure 1. Spores 2, 3, and 8 were removed separately, spores 6 and 7 remained attached to each other and

were removed from the ascus together, and spores 1, 4, and 5 failed to germinate on the agar. Mycelia from the three single spores were crossed in all possible combinations. Mycelia of spores 6 and 7, grown together, produced no apothecia, but when grown with the mycelium from spore 2, fruiting bodies developed, indicating that it was spore 7 rather than spore 6 which had germinated. Though all of the spores from this ascus were not available, those that germinated were in their proper order in the ascus. The results shown in table 3 and figure 1 indicate that spores 1, 2, 5, and 6 are of one strain, while spores 3, 4, 7, and 8 are of the opposite strain. It is evident that sex segregation in ascus B takes place at the second division of the zygote nucleus.

In ascus C, spores 2 and 3, 4 and 5, 6 and 7, were removed in pairs, while spore 8 was picked up separately. Spore 1 was lost. Each of the spore combinations, 2 and 3, 4 and 5, 6 and 7, produced apothecia, indicating that spores 1, 2, 5, and 6 are of one sex, while spores 3, 4, 7, and 8 are of the opposite sex. In ascus C, the segregation of sex factors is at the second division, as in ascus B.

In ascus D, spores 1, 2, 3, and 4 were removed together and allowed to germinate. Apothecia developed from this combination. Spores 5, 6, 7, and 8 were also picked up together. After germination, they, too, produced apothecia. The spores of ascus

E were removed in the same manner with similar results. This indicates that sex segregation in neither ascus took place at the first division of the zygote nucleus but occurred at the second or third divisions. Since segregation of the sexual factors in asci B and C is definitely shown to occur at the second division, it is presumed that such is the case in asci D and E. Therefore, the segregation of the factors for sex in the asci designated C, D, and E is as diagramed for ascus B in figure 1.

The results obtained with the five asci indicate that in Ascobolus geophilus sex factors are segregated at either the first or the second division of the

zygote nucleus.

### SUMMARY

Ascobolus geophilus Seaver is heterothallic, since the mycelium from a single spore will not develop apothecia unless crossed with the mycelium from a spore of the opposite strain.

Four spores from a single ascus are of one strain

while four are of the opposite strain.

Segregation of sexual strains takes place at either the first or the second division of the zygote nucleus.

# THE TRACHEAL ELEMENTS IN THE FERNS 1

Mary C. Bliss

THE EARLIER botanists used the term "vessels" rather loosely as referring in general to the conducting elements of the vascular tissue, but it seems clear that in some cases at least the elements referred to as vessels were typical tracheids. Such for example are the "Treppengefässe" of Weiss (1878) illustrating the conducting elements of Lycopodium. The tracheal elements of the Ferns are referred to by most writers as tracheids, although Gwynne-Vaughan (1908) concludes that the tracheal elements in many ferns are vessels. The present investigation was undertaken to examine in detail the tracheal elements of representative types of the eusporangiate and the leptosporangiate ferns as classified by Eames (1936). These types include twenty-four genera of eight families as follows: Botrychium of the Ophioglossaceae, Angiopteris of the Marattiaceae, Osmunda and Todea of the Osmundaceae, Gleichenia of the Gleicheniaceae, Lygodium of the Schizaeaceae, Alsophila and Cyathea of the Cyatheaceae, Cibotium and Dicksonia of the Dicksoniaceae, and fourteen genera of the Polypodiaceaenamely, Adiantum, Asplenium, Blechnum, Davallia, Drynaria, Dryopteris (Nephrodium), Nephrolepis, Onoclea, Pellaea, Polypodium, Pteridium, Pteris, Thelypteris, and Woodwardia.

True vessels are characterized by specialization in the terminal portion of the element and this specialization is expressed in the development of definite, usually large, openings of various kinds and usually also by the angular orientation of the end walls with respect to the side walls. Interpreted in harmony with this definition of the vessel, true vessels exist in Pteridium latiusculum (Desv.) Maxon (Pteris aguilina L.). The first statement of this fact as far as I can determine was made by Russow in 1873. Sachs (1874), DeBary (1884), and Strasburger (1891) figure these vessels in several aspects, and the observations of these early anatomists have been confirmed by Jeffrey (1917). Figure 1 shows the vessel element in Pteridium latiusculum isolated from macerated material of the stem. The side wall facing the observer is marked by scalariform pits through which the pitting of the opposite side, irregular because of contact with parenchyma cells, is visible. The end walls are clearly at definite angles with the side walls. Figure 2 shows a higher magnification of the terminal portion of a vessel element in which the scalariform perforations of the end wall are evident. In an earlier paper (Bliss, 1921), the writer figured portions of these vessels in section showing clearly the difference between the side and end walls (fig. 3).

Typical vessels, in which the scalariform perforations of the end wall are also evident, are present in the root as well as in the stem of *P. latiusculum* (fig. 4, 5). In these figures the end wall is comparatively

<sup>1</sup> Received for publication June 6, 1939.

short, but in some cases the perforated area is very long. In one element, for instance (fig. 6), the writer counted 160 perforations; this indicates that the end wall must have met the side wall at a very small angle, and the area of contact must have been extensive.

Through the courtesy of Professor Jeffrey of Harvard University the writer was able to investigate another species of *Pteridium* which he had collected in Australia—namely, P. esculentum (Forst.) Nakai. In this species, which is closely related to P. latiusculum, vessels are also present in abundance. The elements vary in length, are clear cut in section, and are characterized in general by narrow scalariform bordered pits in the side wall and scalariform perforations in the end wall which is definitely at an angle with the side wall (fig. 7, 8). In a study of the material of both these species in root and stem, it is interesting to note that there are many cells that may be interpreted as transitional between the tracheid and the vessel element. In contrast to the typical vessel element where the end wall stands definitely at an angle with the side wall, there is often a cell that is a vessel element that tapers gradually to a point as does the tracheid and in which the area of contact between the contiguous elements in the terminal perforated region is much more extensive than it is in a typical vessel. This condition is evident in figure 9. There is every gradation from this very long end wall to the short end wall, oriented almost at right angles to the side wall and showing as few as six perforations. These conditions offer a possible explanation of the origin of the vessel from the tracheid in this genus.

Following the investigation of Pteridium, nine species of Pteris were studied. In none of these was there evidence of vessels such as have been described for the two species of Pteridium. The elements were in all cases extremely long, of medium width, and narrowly tapering at the ends. These observations on the length and width of the tracheal elements in the Ferns confirm those made in this group by Bailey and Tupper (1918) in their study of the comparative length and width of the tracheal elements of the vascular cryptograms, Gymnosperms, and Angiosperms. Figure 10 illustrates the type of tracheal element characteristic of the genus Pteris L. In most cases the lateral wall is marked by a single series of elongated slit-like, scalariform pits, uniform throughout the length of the element. There are undoubted instances of serial and irregular pitting in the lateral walls of the element as noted by Gwynne-Vaughan (1908), but in many cases, if traced far enough, the type of pitting is seen to be related to the fact that the element is overlain by parenchyma cells and is not here in contact with another tracheal element.

Following the investigation of the genus Pteris L., thirteen other genera of the Polypodiaceae were examined—namely, Adiantum (Tourn.) L., Asplenium L., Blechnum L., Davallia Sm., Doodia Br.,

Drynaria Bory, Dryopteris Adanson (Nephrodium Rich.), Nephrolepis Schott., Onoclea L., Pellaea Link., Polypodium (Tourn.) L., Thelypteris Schmidel, and Woodwardia Sm. In general, the tracheal

elements are typical tracheids, very long, with sharply tapering ends. The lateral walls are usually marked by narrow scalariform pits. But in all of the genera investigated there was a tendency toward more or less irregular pitting on the lateral walls, the pits being small and circular or elliptical in outline. Various writers on the subject refer to Russow and to the fact that he found true vessels in the root of Nephrodium Filix-mas as in Pteris aquilina, because the end wall was perforated. These writers quote Russow incorrectly, as will be seen from the following excerpt from Russow's work. "Erwahenswerth ist das Vorkommen von wirklichen Gefässen in der Wurzel von Athyrium Filix-femina: die Enden der Gefässzellen sind leiterartig durchbrochen, ganz entsprechend der Perforation bei Pteris aquilina." (Christensen, 1906, gives Nephrodium Filix-femina as a synonym for Athryium Filixfemina.) This statement by Russow is the only one that the writer has found in the literature that asserts, as the result of original investigation, that there are vessels in Athyrium Filix-femina (L.) Roth (Nephrodium Michx.) similar to those found in "Pteris aquilina." In my study of macerated material and sections of the stem of two species of Nephrodium, N. denticulatum Fée, and N. mólle (Jacq.) R. Br., now respectively Dryopteris denticulata (Sw.) O. Ktze. and Dryopteris dentata (Forsk) C. Chr., there is no evidence of perforations in the end wall of the element. The xylem elements taper to a point, dove-tailing into one another, and the side walls are characterized by narrow scalariform pits.

Only one genus of the Polypodiaceae examined, Woodwardia Sm., showed in the tracheal elements any marked variation from those observed in Pteris L. Here the tracheids are characterized by comparatively blunt ends and are much shorter and wider than in most of the genera investigated. The lateral walls are especially conspicuous because of their marked irregular pitting. Figure 11 shows, at the right of the photograph, the terminal portion of one of these elements. Examples of this phenomenon could be multiplied, but the element figured will serve to illustrate a condition which is very common in the tracheal elements of this genus. It is an interesting fact that in the smaller branch veins, the narrower tracheids are characterized by scalariform pits, a condition which one would expect to find in the younger bundle.

In the genus Angiopteris Hoffm. of the Marattiaceae and in the genus Lygodium Sm. of the Schizaeaceae the tracheids are typically scalariform and taper gradually at the ends. In Cibotium Kaulf. and Cyathea Sm. of the Cyatheaceae and in Alsophila R. Br. and Dicksonia L'Her. of the Dicksoniaceae the tracheids are in general entirely scalariform but round or elliptical pits are not uncommon (fig. 12). There is no evidence of vessel structure.

The vascular elements of Gleichenia of the Gleicheniaceae are larger in diameter than those of many of the genera investigated and as a specialized vine type offered an interesting possibility of a more advanced condition in the tracheal elements, but here again there was no evidence of vessels. The tracheids are clearly scalariform and tapering at the ends.

I have left to the last the consideration of the two families, Ophioglossaceae and Osmundaceae, since these groups possess features in the vascular cylinder of the stem that are characteristic of the vascular cylinder of the seed plants. In the Ophioglossaceae as illustrated by Botrychium Sw., we have an advanced type of vascular cylinder: siphonostelic with collateral bundles, endarch xylem, and a small amount of secondary wood formed by the activity of a cambium. This type of central cylinder is not found in any living representatives of the true ferns and represents the mode of organization of the central cylinder characteristic of the stem of the seed plants. Although the topography of the cylinder is advanced in structure, I find no evidence of vessels. The tracheal elements are tracheids which resemble in a striking manner the tracheids of the Gymnosperms by the presence of fairly typical bordered pits. These observations confirm those of Wright (1920) that "the uniseriate and biseriate pits in Botrychium are large, round to oval in shape with a centrally placed pore.'

The woody cylinder in the Osmundaceae is also advanced in that the ectophloic siphonostele is made up of endarch collateral bundles but these are without secondary growth. Gwynne-Vaughan (1908) holds that the xylem of the Osmundaceae consists of true vessels, and he further states that the prevailing idea that the elements in question are tracheids is erroneous. Gwynne-Vaughan bases his conclusions on evidence derived from an investigation of Osmunda (Tourn.) L. and Todea Willd. He states that "there is no pit membrane closing the pits and separating the cavities of the contiguous tracheae from one another (the term 'tracheae' here refers to the elements generally interpreted as tracheids) and that the pits are in fact actual perforations." Conditions similar to those figured by Gwynne-Vaughan are seen in the transverse section of the xylem of Osmunda cinnamomea L. (fig. 13), where absence of the pit membrane is seemingly apparent in the slitlike openings in the walls of the tracheids. Sinnott (1910) also, in a similar section of the xylem of Todea hymenophylloides, shows the same condition of apparent absence of the pit membrane in the walls of some of the tracheids, while in others the pit membrane is clearly visible. The presence or absence of the "split" between the walls of the tracheids, according to Halft (1910), is due to the amount of cohesion between the bars of secondary thickening. Gwynne-Vaughan's paper is well known and need not be discussed in detail here, especially since later writers, Halft (1910), Bancroft (1911), and Wright (1920) have shown that Gwynne-Vaughan's conclusions are incorrect. By means of careful micro-chemical tests and physical experiments they have demonstrated that, with the exception of those types already mentioned, the pit membrane is present in the end wall and in the side wall of the xylem elements of the majority of ferns, including the Osmundaceae. In fossil types the absence of the pit membrane as noted by Kidston and Gwynne-Vaughan (1907, 1908) and Kershaw (1910) may, according to Seward (1898, 1910), be due to the action of ferments secreted by fungi or may be caused by the contraction and splitting of the membrane during drying or decay.

My investigation of Osmunda (Tourn.) L. and Todea Willd. shows that the tracheal elements under discussion are not markedly different from those found in the other genera. Serial pitting is not uncommon, but the elements are in shape characteristically tracheids with narrowly tapering ends (fig. 14). In the macerated material the dissolution of the walls of the tracheid into spiral bands several bars in width, described by Gwynne-Vaughan (1901) for Loxsoma R. Br., is clearly evident. The branched and nodal tracheids described by Boodle (1901) for Lygodium Sw. and Trichomanes Sw. are very numerous in Osmunda cinnamomea L. and O. regalis L. The most common form is the bifurcate type with the branches strongly divaricate, but often the branches are branched again, so that there is an interweaving of branch-tips which makes the separation of the individual elements difficult. Extreme examples of two of these branched tracheids are seen in figures 15 and 16.

#### SUMMARY

True vessels exist in Pteridium latiusculum (Desv.) Maxon and in P. esculentum (Forst.) Nakai. These vessels are characterized by narrow scalariform bordered pits in the side wall and scalariform perforations in the end wall.

The tracheal elements of all the ferns investigated, with this exception, are tracheids. The tracheids are in general scalariform, but a tendency to serial and irregular pitting on the lateral wall is not uncommon.

Since various investigators have shown that the pit membrane is present in the side wall and in the end wall of the xylem elements of the majority of ferns including the Osmundaceae, Gwynne-Vaughan's conclusion that these elements are true vessels is incorrect.

An interesting condition observed often in the root and stem of Pteridium is that of tracheal elements that taper to a sharp point as in a typical tracheid and that have an extensive and clearly perforated area of contact between two contiguous elements. Every gradation is found between this very long end wall and the very short end wall oriented almost at right angles to the side wall as in the typical vessel. This condition may be regarded as transitional between the tracheid and the vessel in this genus.

# CHANGES IN INTERCELLULAR RELATIONSHIPS DURING THE GROWTH AND DIFFERENTIATION OF LIVING PLANT TISSUES <sup>1</sup>

Edmund W. Sinnott and Robert Bloch

The processes of growth and differentiation in multicellular plants involve changes not only in individual cells but in intercellular relationships. Young meristematic cells, all much alike in size and character, soon become differentiated into a wide variety of elements. Some remain small, others increase in volume even to several thousandfold. Some become elongated, others flattened, and others modified in various ways. How the changes which take place in one cell are related to those in neighboring cells is evidently an important problem, since it involves the more general question as to the developmental relations of cell and organism.

As to how the intercellular readjustments made necessary by differentiation are brought about there is no general agreement. Several possibilities suggest themselves. (1) Cells might slide along the surfaces of their neighbors and thus alter their positions. This commonly occurs in animal development, where cells may migrate for some distance. Ever since the work of Krabbe (1886) and other early students of the problem, a number of botanists have presented evidence that such "sliding growth" occurs in plant tissues, though this has been seriously questioned by others. (2) Some cells might cease division and begin expansion while their neighbors were still dividing, and thus become relatively large and make contacts with an increased number of cells. This method is certainly operative in many cases, though by no means in all. (3) Adjustments might be brought about by differential growth within cells, one portion of a cell exactly keeping pace with a rapidly growing neighbor cell and another portion with a more slowly growing cell, so that different parts of the same cell would thus grow at different rates. Such unequal or localized growth certainly takes place in root hairs, tyloses, and other tissues where one portion of the cell is free, but is more difficult to demonstrate in cells which are surrounded by others. (4) For a brief period when cells are very young and their walls may still be subject to surface forces, readjustments in length and relative position of the walls may take place which do not involve either sliding or differential growth in the strict sense of these terms.

It is often difficult to determine by a study of sections of killed material alone (the method heretofore chiefly employed) which of these possibilities of intercellular readjustment are actually operative. To obtain convincing evidence, it is obviously necessary to make successive observations of a group of cells in their living condition as they grow and differentiate. The purpose of the present paper is to bring

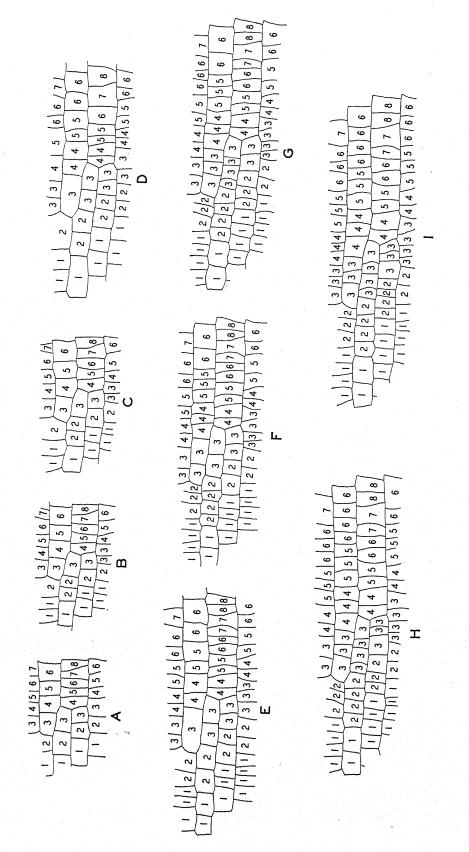

<sup>1</sup> Received for publication June 7, 1939.

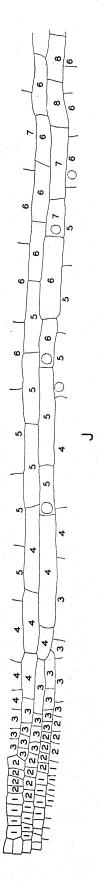

This investigation was carried on by the aid of a grant from the Special Fund for Research of Columbia University. forward such evidence from a study of the developing surface layer of the root in a number of species.

Methods.—One of the authors (Sinnott, 1939) has recently described a technique by which it is possible to study living plant meristems directly. Seeds of certain small-seeded grasses are grown on damp lens paper in moist chambers. The terminal root meristems are sufficiently translucent so that the cells of the outermost layer and the one directly beneath it can be observed under high magnifications. The members of a group of young meristematic cells, and of all their descendents, may be identified in this way from their earliest condition near the extreme tip of the root, through the period of cell division and cell enlargement until their final size is established and differentiation is complete, a process occupying from 24 to 48 hours. By successive camera lucida drawings made at intervals, a complete record may thus be obtained of every cell in an entire cell lineage, both as to its own changes and as to its relations with neighboring cells.

Roots of Phleum pratense, Poa trivialis, Sporobolus cryptandrus, and Chloris gayana were the ones chiefly studied. Aside from the fact that it can be observed in the living condition, such material has certain other advantages. The cells are rectangular and in regular longitudinal rows. Cell divisions in the surface layer (the tissue chiefly studied) are all anticlinal and with rare exceptions are at right angles to the long axis of the root. Cell enlargement is entirely in the longitudinal direction. A considerable degree of differentiation occurs, for the cells which are to develop root hairs are in many respects unlike those which do not do so. In Phleum and Poa this differentiation is more pronounced and occurs earlier than in Sporobolus and Chloris (Sinnott and Bloch, 1939). The exact points of origin of new cell walls, the increase in size of individual cells, and any alterations in the relationships between cells, can thus be studied under the simplest of conditions and can be expressed in quantitative terms.

RESULTS.—The basic results can be set forth most directly by presenting a series of drawings of the same group of cells at successive intervals from early development to maturity. This has been done for a group of surface cells in two roots of Phleum pratense in figures 1, A-J, and 2, A-D. In the first drawing in each root every cell is given a number, and since a region was always chosen in which one or more distinctively shaped cells were present, the original cells or their descendants can always be identified in later drawings. After division has ceased, all the cells elongate greatly, but they show no change in their transverse dimensions. It will be observed that numerous cell divisions occur and that following the last division the apical daughter cell ordinarily develops a root hair but that the basal one

does not. These presumptive root-hair cells grow less rapidly than do the hairless cells so that there is a considerable increase in diversity of cell size in mature tissues as compared with the meristem.

"Sliding Growth."—This increasing difference in relative cell size makes it possible to determine with some certainty whether or not the cells are sliding along one another. A study of the figures will make it clear that the position which a new cross wall assumes, with reference to the cross walls in the two adjacent rows, is essentially maintained throughout development and persists even when the cells are many times their original length. If sliding growth were to occur, the end wall of one cell should occasionally be seen to move past the end wall of its neighbor in the next adjacent row. This was never found to be the case, however, even though end walls in adjacent cells are sometimes laid down rather close to one another. Sliding growth would also be demonstrated if the distance between the end walls of two adjacent cells were ever seen to grow less, even though the change were not enough to carry the two walls past each other; but although distances between end walls of adjacent cells change markedly during development, this change always involves an increase rather than a decrease in the distance between them. In some cases of abnormal growth, as in the root treated with 0.02 per cent solution of colchicine (fig. 3), the cell walls grow very unevenly, and the distance between adjacent cross walls may fail to increase significantly even though the rest of the cell expands greatly; but it never decreases.

Throughout elongation, in this cell layer and characteristically for similar plant tissues in general where cells are in regular rows, each cross wall in one row tends to be opposite the middle of the adjacent cell in the next row and very rarely or never opposite another cross wall. In other words, the cells "break joints." If sliding growth took place, however, this characteristic behavior would not occur, for there should then be no relationship between the positions of the walls in one row and those in the

This same constancy of relationship is observable between cells of the surface layer and those immediately beneath it. Figure 4 is a drawing of a number of cells in these two layers near the meristem, and of the same cells during elongation and when fully expanded. Slight apparent changes in relationship will appear in such cases if the angle of observation is not exactly the same, but it is clear that the relationship of cross walls in the upper layer to those in the lower layer remains essentially constant.

Additional evidence that the wall of one cell does not slide along that of its neighbor is obtained from a study of the wall itself. In *Phleum* and *Poa* the presumptive root-hair cells (trichoblasts) are early differentiated from the hairless cells in a number of

respects. They are smaller, grow less rapidly, and are more richly protoplasmic. In the living condition their walls seem much like those of the hairless cells; but if the roots are treated with concentrated potash, the walls of the young root-hair cells tend to retain their firmness, whereas the longitudinal walls of two adjacent hairless cells become shortened and wrinkled (fig. 5A). It is significant that when a root-hair cell is in contact with a hairless cell, the longitudinal wall of the latter does not wrinkle, as it would do if free to slide along its neighboring cell, but retains its smoothness as it would do if tightly adherent to the much firmer wall of the root-hair cell (fig. 5B).

All the evidence, therefore, indicates that in this material, at least, the cells do not slide along one another but are held so firmly together that points in adjacent cell walls which are originally opposite each other are still opposite after these cells have

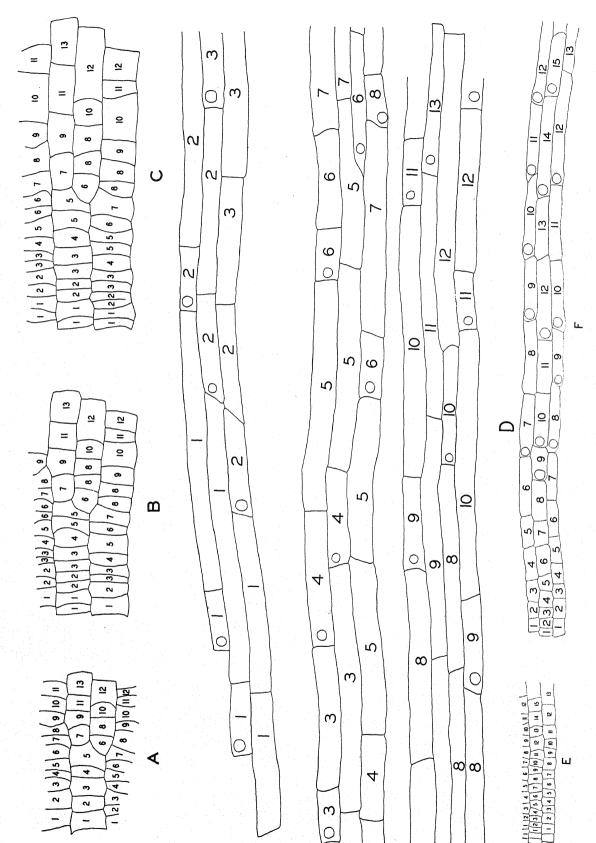

greatly elongated.

Differential wall growth.—If cells do not slide along each other, then the changes in intercellular relationships which arise after cell division has ceased must be due to differential cell growth. This will express itself primarily in differential growth of the cell walls. To determine whether this occurs and to compare the growth of various parts of a single cell, one must be able to identify specific points on the cell wall and to measure the distances between them at successive periods during growth. Since the walls of most thin-walled cells, such as the ones here studied, appear externally homogeneous, it seems difficult to find, such marker points within the cell itself. If adjacent cell walls are firmly fastened together, however, as they seem to be, and if they increase in length synchronously and without sliding, then the points along a given cell wall where the cross walls between its neighboring cells abut upon it may be used as constant measuring points. When the distances between such points are measured during growth, it becomes clear that the cell wall is expanding at different rates in different

This is most obvious, of course, in a comparison between the transverse and the longitudinal walls. The former do not grow in length after they are first laid down, but the latter may elongate thirtyfold or more. This marked difference occurs in any plant tissue like this where cell enlargement is primarily in one dimension rather than in three.

Elongation of the longitudinal walls, however, does not proceed at a uniform rate but may be shown to be more rapid at some points than at others. Various factors are evidently involved. First, if two cells are growing at unequal rates, then an adjacent cell which is in contact with both of them must evidently be growing faster opposite the faster growing cell than opposite the slower one. The root-hair cells grow somewhat less rapidly than the hairless cells,

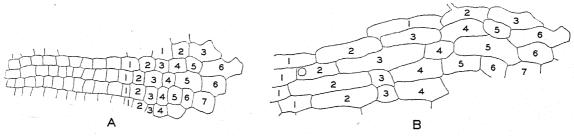

Fig. 3. Phleum pratense. Surface cells from a root treated with 0.02 per cent solution of colchicine, showing differential wall growth but persistence of original relative positions of cross walls. A, December 20, 11 a.m. B, December 21, 11 a.m. (×190).

and they evidently check the growth of cells adjacent to them. For example, cell 5, left, in the middle row of figure 2D is in contact with three cells in the row below it—5, 6, and 7. The first and third are hairless cells, but 6 is not. A comparison of figure 2D with B and C shows that the lower longitudinal wall of 5 has elongated much more rapidly at its ends, opposite cells 5 and 7, than in the middle, opposite 6. Similarly, the upper wall has elongated much more opposite cell 5, a hairless cell, than opposite cell 6, a root-hair cell. Similar relations can be found

(cf. fig. 2, C and D). This can be determined here because there is a marker relatively near one end of the cell. The upper wall of this same cell, marked in the middle, grows about equally on both sides of the marker, but this tells us nothing as to the growth near the ends as compared with the middle. The slower growth near the end walls is more pronounced in certain roots and under certain conditions. Thus in figure 2E, F, where size differences between cells are less pronounced, the growth of the cells is so much greater in the middle than at the ends that the

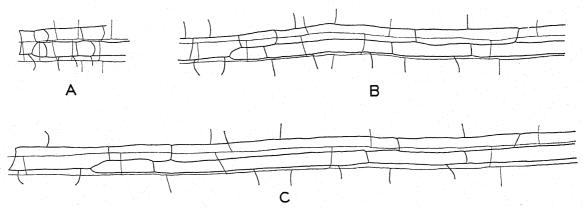

Fig. 4. Phleum pratense. Three stages showing the growth of the surface layer of cells (heavy line) and of the cell layer immediately beneath it (lighter line). The original relationships of the cross walls are essentially maintained during cell expansion. A, April 28, 12 m. B, 4 p.m. C, April 29, 10 a.m. (×255).

throughout. These differences in growth necessarily follow if cells are growing at different rates and if their walls do not slide past each other.

A second factor in differential wall elongation is the influence of the cross wall. In many cases, and especially under certain conditions, wall growth in length is much less in the vicinity of the end wall than in the middle of the cell. Thus in the middle row of figure 2D, cell 4 is cut by the wall between cells 5 left and 5 right below, and rather near its apical wall. This part of cell 4 (between the 3-4 wall, middle row, and the 5-5 wall below) evidently has grown much less rapidly than the rest of cell 4

cross walls in adjacent rows at maturity tend to fall almost in a row across the root, although when laid down they were each nearly opposite the middle of the adjacent cells. This condition seems to occur frequently in roots where growth is stopped or temporarily slowed down owing to age or repeated use for observation, or because of periodic changes in external conditions. In such cases considerable radial swelling of the growing region may take place, involving a certain amount of expansion of the cross walls.

A third factor in differential cell elongation is the gradient in expansion which progresses from the

base of the root toward its tip. If a given group of cells in one row is carefully observed from the time

when cell division stops until elongation has ended, it will be seen that in each cell the basal (proximal) portion, as measured by marker points along it, grows more rapidly at first than the apical (distal) portion, and later that the apical portion grows faster than the basal. This same result is progressively visible in the successively more apical cells of the row. It is as though there were a "wave" of elongation rolling down the root, reaching its crest in one end of the cell first and then passing on to the other, the amplitude of the wave extending over the whole region of elongation. Since one cell occupies only a small part of this zone of extension, the differences between its two ends are not very conspicuous, but careful measurement reveals them.

This can best be studied in a form like Sporobolus where there is no marked differentiation between root-hair cells and hairless cells in early development. Figure 6A-C shows a group of cells, from a root of this genus, extending from the apex well into the region of elongation. In table 1 are given the percentage lengths of marked basal and apical ends of various cells in this figure, measured at six successive periods, only three of which are here figured. Measurements are made from one end of the cell to the point opposite a cross wall in the adjacent row. It is evident that at first the basal end gains faster than the apical and then the apical faster than the basal, the final proportion between the two being essentially like the original proportion. This may be seen, for example, in cells 5 and 6 of the middle row. The older cells, at the right in figure 6, have gone through both phases, and the original relations to their neighbors are restored. The much younger cells at the left are just entering the wave of enlarge-

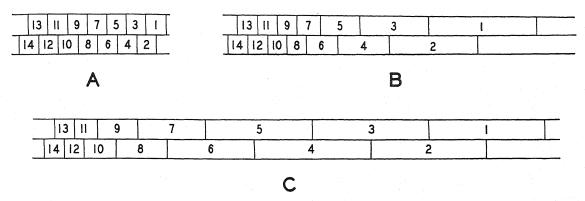

Fig. 7. Diagrammatic representation of the "wave" of elongation in a group of cells similar to those in fig. 6. A, cells of meristem before beginning of expansion. B, cells 1-7 have elongated more at their basal ends than at their apical ends. C, cells 1-5 have elongated more at their apical ends than at their basal (as compared with B), thus tending to restore the original proportions of the wall; cells 6-11 are now in the stage of greater basal growth.

ment, and their basal ends are growing more rapidly than the apical ones. There are slight irregularities in certain cells, probably due to errors in drawing, but the general behavior of the cells is as previously described. A diagram of three stages in elongation, with the changes considerably exaggerated, is shown in figure 7.

The same result is evident in the cells of *Phleum*, but here it is masked somewhat by the different growth rates of root-hair and hairless cells. In *Sporobolus*, also, when differentiation of these two types of cells begins to occur, just after the third stage here shown, the effect of the "wave" is much less obvious. It seems probable that the type of differential cell growth here described is characteristic of all similar tissues which are elongating by cell enlargement. If cells do not slide along each other, and if there is a gradient in root elongation, one end of a cell must evidently grow at a different rate from the other.

Discussion.—Of the four possible methods mentioned earlier in this paper by which changes in cellular relationships may be achieved, three seem inoperative in the tissue here studied. Differential duration of cell division does not occur; growth differences arise when the cell walls can no longer be modified by surface forces; and sliding growth seems to be eliminated. Differential cell growth is thus apparently the method by which intercellular adjustments, due to unequal cell enlargement, are brought about in this case.

Differential wall growth.—The problem in the present material, therefore, is concerned primarily with differential growth of the cell wall, since changes in the size and shape of a plant cell are chiefly related to changes in its wall. Most studies of the cell wall have been confined to single cells and have thrown little light on intercellular relationships. Since a cell is a relatively homogeneous physiological unit, it might be expected that its wall would grow equally throughout. This seems to be rather generally the case as far as wall thickness is concerned. In expansion, however, it is clear that

different parts of the cell may vary considerably. Thus a root hair grows in length only near its tip; and callus and tylosis cells, cambial initials, and certain latex cells show strongly localized growth. Our knowledge of the way in which the cell wall grows is as yet too meager for an understanding of how these local differences in growth are brought about, but that they occur even in unspecialized tissues like those here described seems obvious.

Some of these differences are caused by unequal growth of adjacent cell walls. The walls of the roothair cells, for example, grow less rapidly in length than do the walls of hairless cells. The decreased growth of a hairless cell at the point where it is in contact with a root-hair cell seems primarily due to the fact that the two cells are tightly bound together and that the slower growth of one checks the otherwise more rapid growth of the other. It appears that these differences in growth and differentiation between the walls of root-hair and hairless cells, which become noticeable from the time when both arise from the same mother cell, are associated with differences in the chemical and metabolic character of these cells, as demonstrated by microchemical tests made during the various stages of development. These changes are not always constant, as is shown by the various types of development here described, and they may easily be influenced by alterations in external conditions, such as the action of light or the calcium content or acidity of the culture solution. Normally in a type like Phleum the cells which are to form root hairs are distinguishable at the beginning from hairless cells by their somewhat more meristematic appearance, by their denser protoplasmic contents, and by staining more deeply with Ruthenium Red. As stated previously, their walls appear to be more rigid and tend to swell more with concentrated KOH (fig. 5, B). Both types of cells develop a birefringent cellulose wall which is surrounded by pectic material, but differences develop in the amounts of these materials laid down. The wall of the root-hair cell often tends to become thicker, and polar differences also gradually develop between its proximal end and the distal end, where the root hair arises.

The less rapid growth sometimes observed near the ends of a cell is perhaps to be explained as due to a change in character of the wall and to the amount of material laid down in the corners. In many plant cells the walls are somewhat thickened in this region. In the surface cells of the oat coleoptile recently pictured by Farr and Sisson (1939, fig. 1) it is noteworthy that the ends of the longitudinal walls seem much more rigid than the middle portions.

The differential wall growth within single cells due to the "wave" of elongation evidently results from still another factor. The lengthening of the tissue can best be pictured as due not to successive increase of one cell after the other but rather to the progressive elongation of the entire series of cell walls, sweeping up from the base toward the apex of the root and affecting all the walls at a given level equally, regardless of what cells these walls happen to form a part. The appearance suggests the passage of some stimulus from base to apex or the diffusion distally of some substance stimulating wall growth, independently of individual cells.

It seems clear, at all events, that one of the major factors in differentiation and in the changing intercellular relationships among plant cells during development is the unequal growth of various portions of the cell wall in the same cell. An understanding of how this is accomplished must wait until much more complete knowledge of cell wall development is obtained than is now available.

Other types of differential wall growth.—The material here described has the great advantage that it can be observed in the living condition. It is a comparatively simple tissue, however, with relatively little differentiation, and one would be unwise to draw from it too general conclusions as to the manner in which intercellular readjustments are brought about in other plant tissues. Various modifications

of this general type have been reported.

In many cells, for example, differences in wall growth are much more sharply localized than in the tissue discussed in the present paper. Thus in the crystal cells of *Citrus* described by von Guttenberg (1902) it is clear that during cell enlargement the upper portion of the wall, which ultimately reaches the surface of the leaf, grows very much more than does the lower portion, though both are increasing. A similar behavior of other crystal cells and of hair cells has been reported by Rothert (1900) and Knoll (1905).

Still more extreme is the differential growth of initials of prosenchyma in the secondary tissues of higher plants. Attention was first called by Sanio (1872) to the increase in length of xylem cells in successive annual rings. This increase has been shown by a number of later investigators to be due to an elongation of the cambium cell wall sharply localized at the ends of the cambium cells, the rest of the wall showing no elongation at all. Klinken

(1914) has studied this process by means of serial sections, and Neeff (1914) provides much evidence, especially from stems where cell polarity has been disturbed by decapitation. Bailey (1923) and Bailey and Kerr (1934) have also discussed this type of apically localized cambial cell growth. A somewhat similar type of growth is found in latex ducts of the non-articulate type. Zander (1928) and Schaffstein (1932) among others have shown that the growth of these structures takes place only near their tips, in regions where the other tissues of the plant are still growing.

These cases of sharply localized differential wall growth are thus confined to rather specialized meristematic tissues. They differ only in degree, however, from the simpler cases described in the pres-

ent paper.

Sliding growth.—Wall growth which is thus localized at a small region of a cell, however, or at the two ends of a long cell, necessarily brings about changes in intercellular relationships, since the elongating portion grows in between two neighboring cells and thus often radically changes the cell pattern. This is especially true of elongating cambium cells. It has been clearly demonstrated by Neeff (1914), who presents evidence that the sharp expanding cell tip digests the cementing substance between two neighboring cells, ruptures the protoplasmic connections, and grows between the two cells. The same change possibly occurs near the tips of latex ducts. This type of growth alters the relative positions of cells and is evidently an important factor in certain kinds of tissue differentiation. Unfortunately, it has been referred to by many workers as "sliding" growth, though there is no evidence that the surface of one cell slides over another during the process. The growth of the intruding cell may be thought of as that of a root hair moving through the soil by apical growth, or of a tylosislike structure which pushes out into a mass of tissue instead of into a cavity. The general picture of how such a change in intercellular relations could be brought about without sliding growth is shown in a rather simple case in the diagrams in figure 8, which is modified from von Guttenberg's data. The separation of the two epidermal cells a and b is brought about by the greater growth of the upper portion of the crystal cell c, though all the cell walls are growing somewhat. It will be noted that all points on the cell originally opposite each other remain so except those in the anticlinal wall between the epidermal cells a and b, but that these points, having established contacts with the newly developed portion of the wall of c, retain these connections without later sliding. To distinguish this type of changing cell relationship, the term intrusive growth is here pro-

Of course the possibility cannot be excluded that true sliding growth, where the surface of one cell actually slips over the surface of another, may sometimes take place. Krabbe (1886) in an extensive monograph, comes to the conclusion that sliding

growth occurs in very many plant tissues. He studied secondary xylem particularly, though most of his evidence concerns changes in the relation of vessel cells to adjacent smaller cells as the former increase in diameter. He finds that a vessel initial, originally a member of a regular radial row of cambial cells as seen in cross section, by its enlargement causes adjacent cells to be pulled apart from each other so that the young vessel cell, sliding over their surfaces, finally establishes contact with many more cells than it had at first.

Krabbe's results have not received substantial confirmation. Nordhausen (1897) showed that in many cases which Krabbe cited as sliding growth, the increase in number of cell contacts which a vessel gains as it increases in size is due to continuation of divisions in adjacent cells rather than to separation of cells. A similar explanation will doubtless hold for many other cases, notably the elongating vascular initials near the primary meristem, which ultimately are in contact with very many adjacent pith or cortex cells, the latter having continued to divide transversely for some time after the provascular cells ceased to do so.

Although the possibility of true sliding growth, in Krabbe's sense, cannot be excluded, it seems probable, in view of the evidence in the present paper and from the results of others, that it is rare or absent in most plant tissues and cannot be regarded as

an important factor in development.

Priestley (1930) has endeavored to explain changes in intercellular relationships by assuming the occurrence of what he terms "symplastic" growth, which presumably does not involve sliding. This conception seems to refer to adjustments in the cell wall brought about only at an early stage of cell growth, and therefore cannot be applied to the changes described in the present paper, which often continue throughout the development of the cell.

The issue of sliding growth involves more than a problem in histology, however, for it is connected with the fundamental problem of the relation of the cell to the organism in development. If cells slide along each other, the possibility is open that they may change their original positions and may actually migrate, suggesting the movements of the myxamoebae in the growth of the fructifications of certain myxomycetes. Such a changing relationship would tend to support the conception that the development of the organism is simply the result of complex interactions between the semi-autonomous cellular individuals of which it is composed. If, on the other hand, the cells are tightly adherent (though they may send out intrusive processes into adjacent tissue) the development of such a system could more readily be explained on the assumption of a mechanism inherent in the whole cell complex and not related to the behavior of independent units within it. At all events, any facts which will throw light on the nature of intercellular relationships, even of the relatively simple spatial sort here considered, cannot fail to have an important bearing on the enigma of organic development.

### SUMMARY

The problem of changing intercellular relationships brought about by growth and differentiation was studied in living tissues in the growing region of certain grass roots.

Cellular readjustments observed in this material cannot be due to surface forces, since they appear relatively late, after cellulose walls have been laid

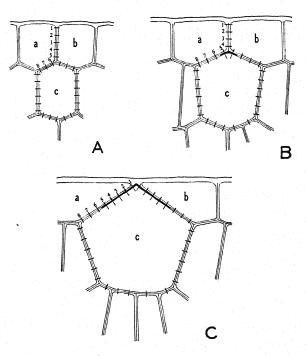

Fig. 8. Diagrammatic representation of the mode of growth of the crystal cells of the leaf of *Citrus* (modified from von Guttenberg), showing the intrusive type of cell growth. See text.

down; nor due to differential cell division, since division ceases in all the cells of a given region at about the same time. They apparently are not due to "sliding" growth, since transverse walls in adjacent longitudinal rows do not approach or pass each other.

Changes in intercellular relationships here observed result from differing rates of growth in different parts of the cell wall. This is evident where a cell is in contact with two others of unequal growth rates; where the ends of a cell grow less rapidly than the middle portion; and where the "wave" of elongation, proceeding toward the root apex, affects one end of a cell before it does the other.

Other more specialized cases of differential walls growth are briefly discussed, such as the more or less sharply localized intrusive growth of certain idioblasts, cambium cells, and non-articulate latex ducts.

Reported instances of sliding growth are reviewed, and it is shown that they may be explained by differential growth of the cell wall.

The implications of these results for the general problem of development are discussed, and the im-

portance of a more extensive knowledge of the structure and growth of the cell wall is emphasized.

## A NEW TIBOUCHINA FROM PERU 1

## H. A. Gleason

Tibouchina incarum Gleason, sp. nov. Frutex ramosus, caulibus strigosis; foliis tenuibus ovato-lanceolatis acuminatis basi cuneatis utrinque pubescentibus 7-pli-nerviis; panicula ramosa glanduloso-hirsuta; hypanthio poculiformi glanduloso-hirsuto; staminibus fere isomorphis, connectivis basi breviter productis; T. Gayanae affinis.

Widely branched shrub to 15 dm. high; stems 4-angled, closely strigose. Petioles slender, substrigose, 1-2 cm. long. Leaf-blades thin, ovate-lanceolate, to 11 cm. long and 4.5 cm. wide, acuminate, minutely serrulate, abruptly cuneate at the base, closely substrigose above, paler and softly villous on the veins and veinlets beneath, 7-pli-nerved. Panicle ample, freely branched, to 25 cm. long, its branches hirsute with chiefly glandular hairs. Pedicels about 2 mm. long. Flowers 6-merous. Hypanthium cupshaped, thin-walled, 4-4.5 mm. long, densely glandular-hirsute. Sepals triangular, often somewhat falcate, recurved, 2.6 mm. long, finely ciliate, sepa-

<sup>1</sup> Received for publication August 1, 1939.

rated by narrow sinuses. Petals bright pink, broadly obovate, 8 mm. long and almost as wide. Stamens nearly isomorphic but differing slightly in size. Filaments 4.7 or 3.7 mm. long. Thecae stoutly subulate, 4.3 or 3.8 mm. long. Connectives prolonged 0.7 or 0.8 mm. Ovary superior, densely bristly at the summit. Style 10 mm. long; stigma truncate.

Machu Picchu, near Cuzco, Peru: in shaded moist hedgerows, alt. 5,000 ft., Balls B 6817 (Type in the Britton Herbarium, New York Botanical Garden); grassy hillside, alt. 8,000 ft., Stafford 772 (Herb. Kew.); grassy slope among shrubs, alt. 8,000 ft., Stafford 791 (Herb. Kew.); open brush formation, alt. 2,200-2,300 m., West 6456 (Gray Herb.).

The species is closely related to *T. Gayana* (Naud.) Cogn., also from the vicinity of Cuzco, in which the leaves are smaller and rounded to subcordate at the base, the sepals proportionately longer, and the pubescence of the hypanthium not glandular.

THE NEW YORK BOTANICAL GARDEN

# CELLULOSE AS A SUBSTRATUM FOR SAPROPHYTIC CHYTRIDS 1

# R. H. Haskins

SINCE APRIL, 1938, collections of saprophytic chytrids have been made from bait placed in ponds near the Thames River on the campus and in a sphagnum bog at North Bay, Ontario. The method of baiting was that used by Karling (1935).

A number of these chytrids are being kept in culture. In general, methods and technique followed are those described recently by Couch (1939) and brought here by Miss Berdan from his Chapel Hill laboratory after the summer of 1938. All cultures have been kept under as nearly sterile conditions as possible in a room with controlled temperature (about 60°F.). Until January 30, 1939, the substrata used were leaves of wheat, corn, rye, oats, other cereal grains, and grasses from which the chloro-

phyll had been removed.

There are some practical disadvantages in their use. One is the necessity of keeping the plants in young stages all year in the greenhouse. Secondly, the thickness of the leaves, the presence of stomata, the epidermal hairs, and even the cell walls often tend to obscure the early stages of growth from the germinating zoospores. Very young, thin leaves are used to offset this, but their tissues break down rapidly, and the cultures require constant care. Even with older leaves, some chytrid species develop so rapidly that water and substratum have to be changed every few days. When several hundred cultures are being kept over long periods, the labor and inconvenience are excessive.

During a conversation in January, 1939, Dr. F. K. Sparrow, Jr., suggested the use of paraffined filter paper as a substratum, following Dr. Rex Webster (Middlebury College, Vermont), who had grown a species of Rhizidiomyces2 upon it. More than fifty years ago, according to Schröter (1889), Rhizophlyctis rosea (de Bary and Woronin) Fischer was found on moist blotting paper by Sorauer in Ger-

OBSERVATIONS.—It had been noticed in our laboratory that most of our forms seemed to thrive equally well in leaves lacking nearly all cell contents as in those (e.g., young wheat) with globules of brown oil. Consequently, lens paper (Cenco) in which the individual fibers could be distinguished under the microscope was substituted for paraffined filter paper. On January 30 a small rectangle of this was added to a healthy culture of Rhizophlyctis

<sup>1</sup> Received for publication June 13, 1939.

The writer wishes to express his thanks to Prof. H. B. Berdan, under whose supervision this work has been done, for advice and criticism, for revision of the manuscript, for reports on chytrids (6) to (10) and use of figures 4, 6, and 10; also to Dr. F. K. Sparrow, Jr., of the University of Michigan, and to Dr. J. S. Karling of Columbia University for their interest and advice.

<sup>2</sup> Since writing this paper it has been learned that Dr. J. N. Couch (1939) grew four species of chytrids on boiled filter paper in 1938, one of these being Rhizophlyctis rosea

and another Rhizophlyctis n. sp.

Petersenii Sparrow (?) which had been collected in London, Ontario, and grown in grass since April, 1938. On February 13, numerous orange sporangia typical of this chytrid were found in the meshes of the paper (fig. 12). The fibers seemed to be partly decomposed, and the rhizoids of the fungus twined loosely among them and even extended out freely

into the surrounding water.

That same day a small rectangle of cellophane (National Paper Goods, Ltd., Hamilton, Ontario, 1937 grade) was added to the culture dish. On February 15, innumerable zoospores in varying stages of germination (fig. 1) could be seen on both upper and lower surfaces of the nearly transparent cellophane by simply changing the focus of the microscope. In from two to three days' time, the thalli seemed to be penetrating into the cellophane by haustoria-like rhizoids (fig. 2). The old zoospore cases were often still attached to the germ tubes, and the fundamental swellings (the incipient zoosporangia) were plainly visible. The young thalli seemed at this stage to be extramatrical except for the tips of the "haustoria" which were apparently dissolving away the cellophane by some enzymatic (?) action comparable to that by which cell walls of leaves are punctured by invading rhizoidal tips. Later the thalli looked to be wholly or partially imbedded in cavities hollowed out of the cellophane (fig. 3). That plenty of nourishment was being obtained was obvious since the thalli duly matured (fig. 13), and the sporangia reached proportions larger than previously recorded (Sparrow, 1937), often measuring over 350 \( \mu \) and having from one to ten exit tubes. When mature, they produced vast numbers of zoospores, and reinfection of fresh lens paper, cellophane, and leaves was readily accomplished. As the cultures on lens paper and cellophane became very old, the substrata were reduced to jelly-like, amorphous masses containing the sporangia. At this stage single sporangia can be teased out easily under the binocular microscope to set up unisporangiate cul-

It was considered advisable to extend the use of these substrata to other chytrids in culture at the time. In all cases, conditions were kept as nearly sterile as possible. The rectangles of lens paper were autoclaved in a dry, stoppered flask. Cellophane was always boiled thoroughly in distilled water just before using. Results are summarized as follows:

Rhizophlyctis Petersenii Sparrow (?).—In some of the gross cultures pronounced, irregular zonations were observed in the cellophane as the rhizoids extended out farther and farther from the original central body of the thallus (fig. 7). In other cases the cellophane around the sporangia was stained a bright rose-pink color for a considerable distance. Sterile blotting paper was similarly stained by the chytrid. Ashless filter paper was tried to insure

Petersenii Sparrow (?). Young thallus with "haustoria" just penetrating the cellophane. Note the old spore case, germination tube (of which there may be several) and swelling (sporangial fundament). Camera lucida drawing. ×690.—Fig. 3. R. Petersenii Sparrow (?). Young thalli in cellophane with rhizoids extending through the cellophane. ×414.—Fig. 4. No. 7. "Colonies"

against this stain being the result of certain impurities in the substratum. In some cases the whole rectangle became a bright orange-pink color due to the masses of orange sporangia plus this surrounding rose stain.

A single spore culture was made by the dilution method, using a capillary tube. Instead of blowing the final spore on to the substratum, it was left in a drop of sterile charcoal water on a sterile slide, and a tiny piece of sterile lens paper was added to this drop. The slide was placed in a sterile moist chamber. In three days' time the paper was examined, and since a single mature thallus showed, the paper was placed in a regular culture dish containing fresh substratum in charcoal water.

From this culture, growth was secured in all the materials mentioned above. All stages of development were seen, including resting spores (fig. 5) and their germination. A paper describing the morphology and development of this chytrid is now in progress. Since our fungus does not comply exactly with Sparrow's (1937) description of R. Petersenii and has not as yet infected insect exuviae, kindly sent us by him, it may prove to be a separate species or possibly R. rosea (de Bary and Woronin) Fischer.

Nowakowskiella elegans (Now.) Schroeter.— This chytrid has been grown in great profusion on both lens paper and cellophane since February 13, 1939. The rhizomycelium often extends out into the water all around the rectangle of substratum, giving a distinctly fuzzy appearance. Figure 11 shows two intercalary sporangia growing in tandem in the water over the upper surface of a piece of cellophane in which the rhizomycelium is growing. In one case on cellophane, the threads grew out to a distance of more than 5 mm. A few of these were pulled off with delicate sterile forceps and placed on a piece of sterilized lens paper (1.5 imes 1.0 cm.) in water. The threads invaded the paper radially from the point of inoculation, giving an appearance remarkably like the growth of higher fungi on agar (fig. 14). Subcultures made from this have been carried since April 1 without any other fungus ever being present. No resting spores were observed.

Nowakowskiella sp.—This species, collected in North Bay, is larger than N. elegans, and the sporangial wall has a brownish color. Single spore cultures were made on February 13 by the method described above. Growth was excellent on both lens paper and cellophane. No resting spores were found.

Diplophlyctis sp.—This form is larger than D. intestina (Schenk) Schroeter which we have grown in Nitella sp. Dr. J. S. Karling, who kindly examined our material, considers it to be a separate species from D. intestina which he has studied intensively (Karling, 1928, 1930, 1936a). Single spore cultures were made on February 16 as before. All stages of growth, including resting spores and their germination, were obtained on both the new substrata. Figure 8 shows numerous mature sporangia on cellophane. The cavities in which they lie are plainly visible.

CO.3—This is an operculate, monocentric form with very large sporangia (fig. 9). The spores are released in a vesicle. Cultures from single spores made as in (1) on February 13 gave abundant growth on both substrata. While it is still being carried in unifungal culture, no resting spores have been found to date.

Septochytrium variabile Berdan.—A strain was established by Miss Berdan (1939) from a single spore germinated on agar in August, 1938. In February of this year the new substrata were introduced by her into cultures of this chytrid. In lens paper the chytrid shows extreme polycentricity. In cellophane this character was somewhat reduced, but when it was shown, the threads of rhizomycelium with secondary sporangia were radially arranged upon the original central body or primary zoosporangium. A cellophane culture, begun on April 11, contained numerous resting spores which were germinating on May 9 as previously described by her.

Catenochytridium carolinianum Berdan (1939).

—This chytrid was the most difficult to grow on the new substrata. It is of the "endo-exogenous" type (Karling, 1936b), and the germ tube penetrates directly into the tissue from the zoospore. Several attempts were made before growth was accomplished on lens paper. On cellophane the spores usually flattened out, turned brown, and died without any penetration being accomplished. However, on May 5 a splendid culture developed, the sporangia producing spores which infected new cellophane. Figure 6

shows a young thallus, on which the sporangium has not yet developed, apparently growing in water outside the cellophane and with only the tips of the rhizoids imbedded in the cellophane. Later the sporangium developed and shed its spores. No resting spores have been observed yet.

No. 5.3—This is an inoperculate member of the Cladochytriaceae collected by Miss Berdan in Chapel Hill, June, 1938. The hyaline resting spores are subtended by a linear row of delicate cells somewhat similar to those described by Butler (1907) for Nowakowskiella ramosa. It grew well on both substrata, forming zoosporangia and resting spores both in the cellophane and on the rhizomycelium extend-

ing out far into the water from it.

No. 7.3—This is another inoperculate member of the Cladochytriaceae, with lemon-shaped to clubshaped sporangia, collected on the University campus by the writer and cultured since October, 1938, by Miss Berdan. It grows unusually well on both substrata, forms resting spores, and appears pale yellow in mass on cellophane. Figure 10 gives an indication of the clarity with which early stages in development can be seen in this form even when bacteria have not been washed off the cellophane. A few threads bearing zoosporangia and growing far out into the water were separated out and placed on the surface of a rectangle of cellophane. Figure 4 shows three separate "colonies" of young germinating zoospores apparently formed when three of these sporangia shed their spore balls which settled en masse upon the cellophane directly below them.

Cladochytrium replicatum Karling.—Lens paper and cellophane were placed in gross cultures containing this chytrid. It grew readily on both. Resting spores were formed.

Discussion.—Up to date, these substrata which consist mainly of cellulose have been used chiefly for the sake of convenience. They are available anywhere and in all seasons or can be transported simply when cultures have to be moved to a new laboratory as often happens during summer session. They are easily sterilized. Lens paper is particularly useful in establishing single spore cultures since the spore tends to be caught in the meshes of the paper. Cellophane is an excellent medium for the observation of early growth stages and for determining whether the tips of rhizoids are blunt or pointed, often a diagnostic feature. Once the chytrid has penetrated into it, bacteria are washed off its slipperv surface much more thoroughly than from other substrata we have used, while rotifers and protozoans develop sparingly in these cultures. Even when successive generations have been supported in it from one to two months' time the water in the culture dish remains fairly clean, and new cellophane may be added during this time without changing it. Also, the rate of growth generally seems slower in these substrata than in the leaves. Consequently, we have greatly reduced the labor involved previous to their introduction. Unfortunately, Pythium, Fusarium, etc., grow on them, so they have no particular value in freeing a chytrid culture from contamination of this type. Also, older thalli which are imbedded in cellophane are not always as easily studied as in leaves.

We are attempting to obtain a similar cellulose product in a form which can be reduced to the consistency of 2 per cent agar and autoclaved. So far all efforts have been unsuccessful. The common solvents are deadly to the delicate chytrid spores. We have been in touch with the research department of the Eastman Kodak Company, the DuPont Company. and the "Cellophane" Division of Canadian Industries. Limited, in the hope of securing viscose, the fluid intermediate product in the manufacture of "Cellophane" cellulose film. It is the sodium salt of cellulose xanthogenic acid dispersed in a dilute solution of caustic soda. Other dispersing agents for cellulose suggested by them are cuprammonium solution, solutions of zinc chloride, and certain of the tertiary amines, none of which has seemed to be practicable in connection with our problem.

It is not possible at this point to define exactly the relationship of the chytrid to these media. The distinction between intramatrical and extramatrical portions of the thallus is not so clearly established as on most other substrata. In lens paper, thalli have been seen to develop in the narrow lumen of a fiber, forcing the walls apart, in which case they would probably be called intramatrical. In other cases the same chytrid develops chiefly outside with only a few rhizoidal branches penetrating into the fibers. There seems often to be more extensive extramatrical growth as the substratum becomes filled with rhizoids of the chytrid and begins to break down. Is this due to the fact that the nutrient material has been used up or that it has become reduced into a substance soluble in the nearby water and consequently used there as food by the fungus? On the other hand, the very early stages (fig. 1, 10) seem to be almost completely extramatrical.

Karling (1936b) describes a case where a zoospore of Chytridium lagenaria Schenk germinated in the water surrounding the host cell to form a rather extensive thallus. He states that when branches of the rhizoidal system come into contact with the host wall and penetrate into the lumen of the cell, such thalli occasionally mature and produce zoospores. This has been a common occurrence during our experiments with these new substrata. Figure 6 shows this particularly well. Here only the tips of the rhizoids are imbedded in the cellophane. In figure 10, the rhizoidal tips appear to be seen through the cellophane, while the young thalli are in the water above it.

The majority of chytrids grow in pollen grains, algae, water molds, apples, dead wood, and roots and leaves of higher plants. The principal substance common to these is plant cellulose. From our evidence it seems reasonable to assume that, for a certain group of saprophytic chytrids at least, certain

commercial cellulose products may be substituted for these natural substrata.

### SUMMARY

Lens paper and cellophane have been used since January, 1939, as substrata for saprophytic chytrids.

Ten species of chytrids have been grown on these substrata. All have produced mature thalli and zoospores which reinfected fresh material.

Six species have produced resting spores. Germination of these resting spores has been seen in three species.

Culture of chytrids on the cellulose substrata reduces labor, keeps cultures cleaner, and shows young stages of development more clearly than other substrata used in our laboratory up to the present.

# SEXUAL HORMONES IN ACHLYA. I. INDICATIVE EVIDENCE FOR A HORMONAL COORDINATING MECHANISM <sup>1</sup>

# John R. Raper

A NEW HETEROTHALLIC ACHLYA.—Since the discovery of heterothallism in the Mucorales by Blakeslee (1904), a number of fungi in the Zygomycetes and other groups have been shown to have a similar type of sexual relationship. Of these fungi a few members of the order Saprolegniales, belonging to the widely distributed water molds, have been reported: Dictyuchus monosporus Couch (1926), Sapromyces Reinschii Jordan (cited in Weston, 1938), Achlya bisexualis Coker (1927), and A. regularis Coker and Leitner (1938). In the course of the present work on hormonal coordination of the sexual process in these so-called heterothallic forms<sup>2</sup> the author has collected ten isolates which comprise a

<sup>1</sup> Received for publication June 14, 1939.

Contribution from the Laboratories of Cryptogamic Botany and the Farlow Herbarium, Harvard University,

The writer wishes to express his sincere thanks to Professor Wm. H. Weston, Jr., under whose guidance this investigation has been carried out, for his stimulating advice and constructive criticism. The writer is also most appreciative of the criticism and many helpful suggestions which he has received from Professor K. V. Thimann and Dr. D. H. Linder, and he is indebted to Mr. R. M. Page for the drawings reproduced here.

<sup>2</sup> A paper planned for publication in the near future will point out a number of constant and characteristic differences between the sexual condition in these partially separate-sexed forms and heterothallism as originally defined.

new species-complex belonging to the genus Achlya. As a large portion of the work reported here has been carried out with isolates of this new species, a description of the species is at first necessary.

Achlya ambisexualis sp. nov. (fig. 1-6).—Mycelium extensive; maximum diameter in water on hemp seed, 4.5-5 cm.; thin and loose. Hyphae slender, 20-65 μ, mostly 40- $50 \mu$  in diameter at base, tapering only slightly to tip. Gemmae abundant, formed by segmentation of vegetative hyphae, usually with diameter equaling that of parent hyphae; rarely branched; intercalary gemmae long, cylindrical,  $30-50 \times 250-2000 \mu$  in size; terminal ones usually tapering to a point; sometimes but infrequently breaking apart to float free in the water. Zoosporangia abundant, usually solitary; long clavate,  $25-40 \times 200-500 \mu$ ; greatest diameter being nearer terminal than basal end. Zoospores 8.5-10  $\mu$ , mostly 9.2-9.6  $\mu$  in diameter, emerging as usual for the genus, encysting at the tip of the sporangium to form a very loose hollow sphere. Oogonia and antheridia formed when sexually compatible strains are brought together. Sexual character of certain thalli variable, reacting as oogonial (2) or antheridial (3) thalli when crossed with strong ♂ or ♀ mycelia, respectively.3 Oogo-

3 This capacity for sexual reversal is a significant feature of the sexuality of this as well as other "heterothallic" watermolds previously described. The term gynandromixis or gynandromictic sexuality is suggested, implying the mixed sexual character of the different sexual strains and the capacity of certain strains to react as 3 and/or 9.

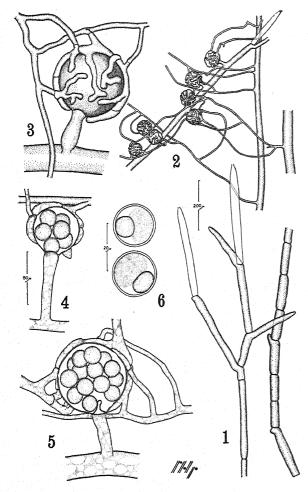

Fig. 1-6.—Achlya ambisexualis. The drawings in fig. 1-15 were made of living material in water with the aid of a camera lucida at initial magnifications of 220, 915, and 2100. For convenience absolute scales are included.—Fig. 1. Gemmae and emptied zoosporangia. ×55.—Fig. 2. Female hypha (left) with oogonia and β hypha (right) with antheridial hyphae—from a mating of β and φ mycelia. ×55.—Fig. 3. Immature oogonium and antheridia. ×225.—Fig. 4-5. Ooogonia in optical section showing oospheres. ×225.—Fig. 6. Mature oospores. ×525.

nia borne rarely intercalary, usually terminal on short lateral branches, 0.25-0.5 times diameter of oogonium, 0.5-4 times as long as diameter of oogonium; spherical in shape, occasionally oblong;  $50-100 \mu$  in diameter, 55 per cent within size 65-85  $\mu$ ; wall thin, less than 1  $\mu$ , smooth with broad pits under antheridia; approximately 50 per cent of oogonia having a blunt, thick-walled projection protruding into the oogonium from the tip of the stalk. Oospores 1-20 in each oogonium, rarely less than 3, mostly 8-14; 20-27  $\mu$ , 64 per cent, 22-24  $\mu$ ; eccentric; usually completely filling the oogonium. Antheridial hyphae much branched, 9-12  $\mu$  in diameter. Antheridia 9-10  $\mu$  in diameter; cylindrical, finger-like, and clearly cut off from antheridial hyphae; much branched, usually almost entirely covering the surface of the oogonium. Always one antheridium and usually many on each oogonium before oogonial delimitation and differentiation of contents to form oospheres can occur.

Seven isolations, all from Charles River at Cambridge, Massachusetts.

Achlya ambisexualis var. abjointa var. nov. (fig. 7-10). -Mycelium compact and dense; maximum diameter 2.3-3 cm. on hemp seed in water. Hyphae 35-70  $\mu$  in diameter at base and of approximately equal diameter throughout except for sharply tapering tip. Zoosporangia 30-50 ×350-600  $\mu$ ; clavate, broadest near terminal end. Spores 10-12  $\mu$ , discharged as normal for the genus, forming a loose hollow sphere at mouth of sporangium. Gemmae exceedingly abundant, formed by segmentation of vegetative hyphae; often branched; commonly breaking apart to float free in the water; terminal gemmae long and sharply tapering.  $330-530 \times 30-65 \mu$  at basal end, tapering to 15-33  $\mu$  near tip; intercalary gemmae much shorter, 110-160  $\times$  30-65  $\mu$ . Oogonia formed sparingly when compatible strains are mated; oogonia terminal on main hyphae or short lateral branches; spherical, rarely oblong; 50-85 µ in diameter, 75 per cent between  $55 \mu$  and  $70 \mu$ ; many with projecting

stalk. Oogonial wall thin and smooth with broad pits under antheridia. Eggs eccentric, 7–20 in each oogonium, 9–13 most common; 17–23  $\mu$  in diameter with 80 per cent between 18–20  $\mu$ . Antheridial branches highly branched and slender. Antheridia finger-like and much branched usually completely covering oogonial wall with their ramifications. Certain plants capable of behaving as either  $\delta$  or  $\mathfrak P$ .

Two collections: Barton Mills, England; Chapel Hill, North Carolina.

Achlya ambisexualis var. gracilis var. nov. (fig. 11-15). —Mycelium loose, diameter up to 3 cm. on hemp seed. Hyphae small, 20-40  $\mu$  in diameter at the base and tapering only slightly to the tip. Zoosporangia plentiful, long clavate, dehiscing as usual for the genus, with the encysted zoospores forming a very loose sphere at the mouth. Zoospores, 10-11  $\mu$ . Gemmae very abundant, formed by segmentation of the hyphae with no noticeable increase in diameter, frequently more than 1 mm. in length, but usually much shorter; not branched and rarely disjointing. Oogonia spherical, thin-walled;  $35-85~\mu$  in diameter, 57 per cent between  $50-60~\mu$ . Oospores eccentric, 3-15 per oogonium, usually 6-10, completely filling the oogonium; 18-

 $27~\mu$  in diameter, with 64 per cent between  $22-24~\mu$ . Antheridial branches and antheridia as in type variety.

Single collection: Blue Hills, Massachusetts.

Achlya ambisexualis sp. nov.—Coloniis in aqua grandibus et effusis, usque 4.5–5.0 cm. latitudine, hyphis 20–65  $\mu$  crassis. Gemmis abundantibus, per partitio hypharum formatis; zoosporangiis et zoosporiis generis propriis. Thallis gynandromictibis. Oogoniis globosis; 50–100  $\mu$ , 58 per cent e 70–80  $\mu$  diametro. Oosporiis 2–20 in oogonio quoque; 20–27  $\mu$  64 per cent e 22–24  $\mu$  diametro; membrana tenui; guttulis oleosis lateraliter positis. Antheridiis gracilibus, multis in oogoniis applicatis.

Achlya ambisexualis var. abjointa var. nov.—A typo differt coloniis angustioribus et laxioribus usque 3.0 cm. diametro, hyphis 35–75  $\mu$  crassis. Gemmis abundantibus, saepe scindentibus. Oogoniis 50–85  $\mu$ , 70 per cent e 55–70  $\mu$  diametro. Oosporiis 3–15 in oogonio quoque, 17–23  $\mu$ , 89 per cent e 18–20  $\mu$  diametro, membrana crassiore.

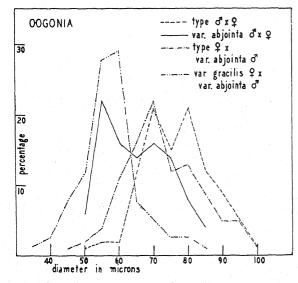

Achlya ambisexualis var. gracilis var. nov.—A typo differt coloniis angustioribus et densioribus, usque 3.0 cm. diametro; hyphis 20–40  $\mu$  crassis. Gemmis gracilibus et longis. Oogoniis 35–85  $\mu$ , 57 per cent e 50–60  $\mu$  diametro. Oosporiis 18–27  $\mu$ , 64 per cent e 21–23  $\mu$  diametro, membrana crassa.

Remarks on the taxonomy of A. ambisexualis.—Achlya ambisexualis belongs to the same section of the genus as A. klebsiana Pieters and the more recently described A. regularis Coker and Leitner. This new species has certain striking characters in common with both A. klebsiana and A. regularis. For example, all these plants are characterized by the formation of gemmae through the segmentation of the vegetative hyphae with very little or no increase in the diameter before or after their formation. A. ambisexualis may be separated from these species, however, by the size of the oogonia and oospores, by minor differences in the morphology of the sexual organs, and by morphological characters of the vegetative mycelium.

In so far as vegetative characters are concerned, A. ambisexualis var. gracilis agrees nicely with the description of A. regularis Coker and Leitner. However, the larger size of the oogonia and oospores, the wider range in size of these organs, and the absence of intercalary oogonia in A. regularis, prohibits the inclusion of this variety under that species.

A plant vegetatively very similar to certain of the isolates of A. ambisexualis was reported from Australia by Crooks (1937). This plant has gemmae characteristic of this species, but it produces oogonial initials which are never differentiated to form oogonia and oospheres. Crooks suggested that her plant was possibly a female strain of a heterothallic species of which the compatible  $\delta$  was lacking and, on the basis of incomplete knowledge of the sexual organs, designated it as Achlya sp. To the writer it seems that this plant is the same as that here described as A. ambisexualis var. abjointa.

Within the complex which is here given specific status, it is immediately obvious that three different varieties are involved. That they are closely related is shown by the fact that the sexual organs of all three varieties are identical except for size. An analysis of the distribution curves for the oogonia

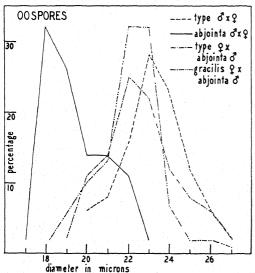

Fig. 16. Distribution curves of oogonia and oospheres of A. ambisexualis and its varieties, abjointa and gracilis.

and oospores of the three varieties clearly brings out these size differences (fig. 16). The type ? mated with the type & produces oogonia falling between  $50-100 \mu$ , with 58 per cent in the range  $70-80 \mu$ , and oospores from 20-27  $\mu$  with 64 per cent within the limits of 22-24  $\mu$ . Matings of var. abjointa type  $\mathfrak{P}$ with type & give sexual organs of the following dimensions: oogonia 50-85  $\mu$ , with 70 per cent, 55-70  $\mu$ ; and oospores 17-23  $\mu$ , with 80 per cent, 18-20 μ. A mating between a \$\pa\$ strain of the type variety and a & of var. abjointa produces sexual structures whose measurements are consistently slightly smaller than those produced in a mating of ô and ♀ plants of the type variety. The curves in the two matings are similar with more than 50 per cent overlap in both oogonia and oospore size. This is to be expected, since the same 9 plant was

used in both crosses, and it is from the  $\mathfrak P$  that both oogonia and oospores arise. A striking difference is seen when the isolate of var. *gracilis* is involved as the  $\mathfrak P$  of the mating pair. The size of the oogonia is nearer that of var. *abjointa*, 35–85  $\mu$ , with 57 per cent between 50–60  $\mu$ , while the size of the oospores more nearly agrees with that of the type variety, 18–27  $\mu$ , with 64 per cent, 21–23  $\mu$ .

Further indication of the close relationship of the three varieties is the fact that they are perfectly compatible in inter-varietal crosses. It is then chiefly a matter of immediate convenience that they are all included here in the same species; further collections of the three varieties and additional experimental work on the sexual relationships will be necessary before they can be given a more final and definite status.

The reason for the specific name ambisexualis is the dual sexual behavior of many of the isolates of this species. Of the ten plants collected, six have been shown to be capable of behaving as either  $\delta$  or  $\mathfrak P$ , depending on the stronger sexual potentialities of the mate.

Introduction and historical background.—In the course of an investigation of the sexuality in the species just described, it became increasingly obvious that initiation and coordination of the different phases of the sexual process were accomplished by diffusible substances. It seemed fitting, therefore, to investigate this phenomenon.

The first demonstration of coordination of the reproductive processes by diffusible substances in the fungi was given by Burgeff (1924) for a member of the Mucorales. In matings of (-) and (+) strains of Mucor mucedo he found that ordinary vegetative growth of the two mycelia stopped shortly before actual contact was established. Into this region, the "restraint area," only a few hyphae penetrated, and certain of these hyphae from each mycelium developed swellings and coralloid branches near their tips to form progametangia even before contact. He considered this characteristic swelling and branching as the initial stage in the sexual reaction and suspected that this effect was brought about by specific chemical substances diffusing between the two mycelia. His classical experiment of growing the two sexually compatible strains on opposite sides of a permeable collodion membrane proved this to be the case, for each of the paired mycelia was sexually activated. This experiment demonstrated that a diffusible substance (or substances) capable of passing through the membrane was responsible for the sexual activation of the plants. The reaction at a distance, induced by diffusible chemical substances, Burgeff termed "telemorphosis." Further, in a number of cases he saw the curvature of the sexual organ initials toward similar organs of the opposed strain, and this he termed "zygotropism."

The work of Burgeff offered the necessary stimulus for extensive investigations in this and other members of the Mucorales. Of the papers describing these investigations many added little or nothing to

Burgeffs results; a few, however, contain significant contributions to the knowledge of the sexual proc-

esses in the phycomycetous fungi.

Verkaik (1930), also working with Mucor mucedo, repeated the membrane experiment but found that only the (+) strain produced sexual organ initials under the experimental conditions. The evidence obtained indicated that only a single substance was involved, originating in the (-) strain and bringing about the formation of zygophores in the (+) strain. This work appears to have been done without adequate controls, and since other investigators have been unable to duplicate her results, its value is questionable.

Ronsdorf (1931), working with *Phycomyces Blakesleeanus* and using the membrane technique, found evidence for two mutually complementary substances interacting between the two mycelia to bring about telemorphotic responses in the two opposed strains. Attemps to extract these substances from the (—) and (+) mycelia were unsuccessful. An interesting point brought out in this work is the effect of histamine, which, when added to the medium, markedly increased the intensity of the sexual reaction. He suggested the possibility of close chemical relationship between this compound and the specific substances involved in the reaction.

Kohler (1935), using Mucor mucedo and the membrane technique, also obtained zygophore formation on the mycelia of both strains. He was unable to determine the origin of the reaction and was uncertain of the number of substances involved.

Krafczyk (1935), in experimental work on Pilobolus crystallinus, considerably advanced the knowledge of the sexual reaction in the heterothallic Mucorales, particularly as regards the hormonal activating and coordinating mechanism. Pronounced telemorphosis and zygotropism were repeatedly observed, and evidence was presented which indicated that the sexual reaction was under hormonal control until the time of gametangial delimitation.

For the aquatic Phycomycetes, the first evidence suggestive of a similar hormonal coordinating mechanism was given by Couch (1926). In working out the sexuality of Dictyuchus monosporus he observed the formation of oogonial initials at some distance from the nearest ô hyphae, other portions of the ? mycelium being in contact with that of the 3. The antheridial hyphae which finally reached the oogonial initials frequently originated from ô hyphae as far as 2 mm. distant, and the antheridial hyphae grew directly toward the 2 organ. Further evidence for diffusible sexual substances was seen in intergeneric matings with Thraustotheca primoachlya. From his observations Couch suspected a hormonal coordinating system and performed a number of experiments designed to reveal the presence of diffusible substances. A modification of Burgeff's membrane experiment was first used with the ô and ? plants separated by a thin collodion membrane; & and P plants were also grown close together in water, but not in actual contact. In both cases the

results were negative, neither of the mycelia giving any reaction.

Working with Sapromyces Reinschii of the Leptomitaceae, Bishop (1937) found definite evidence for diffusible sexual substances. He figured & and ? plants, growing on a semi-solid substrate, with large numbers of oogonia and antheridial hyphae on the and ô mycelia, respectively, in a region where actual contact had not yet occurred. He was further able, by introducing into a culture of the ô plant the water in which a \( \rightarrow \) had grown, to show a considerable increase in the branching of the tips of the ô hyphae; these ramifications he interpreted as antheridial branches. Approximately 3 per cent of the & hyphae showed this response as against 1 per cent in a control culture. The number of substances involved in the reaction, the loci of their production, and their specific actions were not determined.

The mode of growth of the aquatic Phycomycetes is strikingly different on semi-solid media from that of the terrestrial Zygomycetes. In the latter, with the exception of a few forms such as Pilobolus, the growth is almost entirely aerial, with only a limited inter-matrical mycelium. In the case of the aquatic Saprolegniales on the contrary, growth is almost entirely below the surface of the substrate. This characteristic manner of growth renders these submerged forms more amenable than members of the Mucorales to experimentation involving diffusible substances. In the latter the parts of the mycelium which give a sexual reaction and from which the specific substances would presumably arise, are normally above the surface and surrounded only by a film of water. In the case of Pilobolus, which grows submerged in the substrate and is not subject to this generalization, the ease with which diffusion experiments can be made compares favorably with similar experiments for those forms which are characteristically aquatic.

Because of the incompleteness of results and the limited scope of previous work on the coordinating mechanism in the sexual reaction of the aquatic Phycomycetes, the need for a more extensive investigation was apparent. For the purpose of such a study, Achlya bisexualis and A. ambisexualis were beautifully suited. Their manner of growth, the ease and simplicity of technique with which they can be cultured and employed in experimentation, and particularly the strong sexual affinities of certain of the isolates of the latter species made them the ideal experimental plants. The objectives of the investigation have been (1) the demonstration of hormones operative in initiating and coordinating the different stages in the sexual process and (2) the determination of the number of specific substances involved, the points of their origin, and the specific reactions which they induce.

The present paper presents those lines of evidence which indicate a hormonal coordinating mechanism in the sexual reaction of *Achlya*, and the probable mechanism is described. A second paper, planned for the near future will give an account of work con-

clusively proving the existence and activity of diffusible substances.

THE SEXUAL REACTION.—In order to present a comprehensible account of hormonal activity in Achlya, it is at first necessary to describe the re-

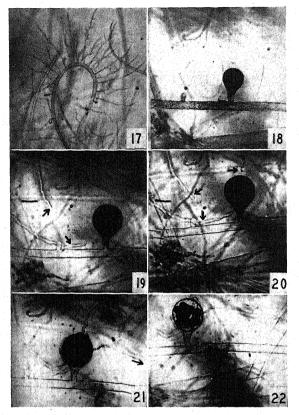

Fig. 17-22. Stages in sexual reaction between  $\beta$  and Q mycelia of Achlya ambisexualis. The photomicrographs here reproduced in fig. 17-27 were made of living material in agar.—Fig. 17. First stage, formation of antheridial branches on  $\beta$  hyphae along line of intermingling of  $\beta$  and Q mycelia.  $\times 30$ .—Fig. 18. Second stage, formation of oogonial initial; two were initiated but only one matured.  $\times 60$ .—Fig. 19-20. Third stage, directional growth of antheridial branches (indicated by arrows) toward the oogonial initial.  $\times 60$ .—Fig. 21. Fourth and fifth stages, delimitation of antheridia (obscure at this magnification) and oogonium.  $\times 60$ .—Fig. 22. Later stage in sexual reaction; the contents of the oogonium have been differentiated to form a number of oospheres toward which grow fertilization tubes from the antheridia.  $\times 60$ .

productive processes in some detail. To illustrate the different stages in the sexual reaction, the development of a single  $\circ$  organ and the accompanying  $\circ$  organs will be traced.

When ô and \$\varphi\$ plants are placed together, the first indication of a sexual reaction is the formation of numerous slender, gnarled, and highly ramified lateral branches on the vegetative hyphae of the ô. These characteristic lateral branches are the antheridial hyphae. They are apparently produced at

random on the  $\delta$  hyphae, and at this stage they certainly show no directional growth toward the P mycelium (fig. 17).

The second stage in the reproductive process is the formation of oogonial initials, first seen as short club-shaped lateral branches on the hyphae of the 2 mycelium. Such a branch elongates slightly, accumulates protoplasm, and begins to swell terminally to form a globose structure. The oogonial initial whose development is followed in figures 18 to 22 was observed two hours before the first photomicrograph was taken, and at that time two small lateral branches of similar size were seen located on the same hypha in proximity. During the two-hour period which followed, the branch to the right (fig. 18) grew and increased in diameter from 20 μ to 50 μ, which represents an increase in volume of approximately twenty times. This increase in volume and an increase in amount of protoplasm continues during a period of 4-12 hours, depending on the environmental conditions. Once the oogonial initial has reached its maximum size of 50-90 μ in diameter, no change is observed during a period of 12-24 hours, subsequent events depending on the accomplishment or failure of the second and third & reactions which follow.

The third stage of the sexual process is initiated when the antheridial hyphae, which at first ramify at random, begin to grow toward the oogonial initials. Figure 19, taken 16 hours after the initiation of the 9 organ, shows two antheridial hyphae approaching the initial. At the end of 17 hours, one of these slender filaments had reached the 9 initial and a third was seen growing toward it (fig. 20). At the end of 21 hours all three of the antheridial branches had reached their objective; upon touching the wall of the oogonial initial they grew in such a way as to become wrapped around that organ. In this particular case the antheridial hyphae originated from ô hyphae at distances of 600  $\mu$ , 530  $\mu$ , and 500  $\mu$  from the oogonial initial, and the path of growth in each case practically coincided with the shortest distances between the points of origin and the ? organ.

The fourth stage in the sexual reaction again concerns the antheridial hyphae. Beginning shortly after they become applied to the oogonial wall, protoplasm accumulates in their tips, and transverse walls delimit the  $\delta$  gametangia or antheridia from the parent antheridial hyphae. This process was completed 21 hours after the oogonial initial was first seen.

The fifth stage in the sexual process follows closely upon the completion of antheridial delimitation. A transverse wall is formed which delimits the large, densely filled portion of the oogonial initial from the stalk and the parent  $\,^\circ$  hypha (fig. 21). The spherical structure thus formed is the oogonium or  $\,^\circ$  gametangium. The formation of the basal wall in the oogonium occurs 24 hours after the initiation of the  $\,^\circ$  organ.

Later stages, including reorganization of the oogonial content to form oospheres, the inward

growth of fertilization tubes from the antheridia (fig. 22), and fertilization, follow, in that order, the delimitation of the oogonium.

While the above is a typical example of the sexual reaction, considerable variations may be seen if a number of cases are followed. The oogonium whose development was just outlined was approached by three antheridial hyphae. Others may attract a much larger number, as many as 86 having been seen growing toward a single \$\pa\$ initial. In such a case the oogonial initial and the numerous antheridial branches approaching it comprise a sphere with the former as its center and the latter forming radii in all planes. A large number of these antheridial hyphae may become applied to the \$\pa\$ initial so that in many cases the entire surface of the oogonium is covered by antheridia.

It often happens, when numerous oogonial initials are produced within a small area, or when the sexual reaction is interrupted, as described below, that antheridial hyphae do not reach the oogonial initials during the time they are receptive. In this case the oogonial initial may be renewed by proliferation. Lateral branches grow out from the bulbous portion of the initial and enlarge at their tips just as did the original. This process may be continued through a number of generations of initials so that from the original a complex of as many as 12 may eventually be formed. During this process there is no apparent increase in the amount of protoplasm, and, as a consequence, most of the initials are supplied with so little protoplasm that they are incapable of developing to maturity as oogonia. In some cases, however, where the process is not carried to such extremes two or sometimes three daughter initials may be functional in a perfectly normal manner after having been reached by the necessary antheridial hyphae.

EVIDENCE INDICATIVE OF A HORMONAL COORDINATING MECHANISM.—That the different stages outlined above are initiated and coordinated by a hormonal mechanism is indicated by the following experimental findings: (1) The sequence of events and the time intervals separating the various phases of the reaction indicate a hormonal mechanism. (2) Incompatibility in inter-specific matings of A. ambisexualis and A. bisexualis involves disruptions of the coordinating mechanism which seem to indicate not only the presence, but also specificity of sexual substances. (3) Variations in the composition of the medium frequently lead to changes in the sexual process which may be interpreted as break-downs in the coordinating mechanism.

In addition to these lines of evidence which point to a series of diffusible specific sexual substances initiating and coordinating the sexual process, telemorphotic reactions occur in both 3 and 9 plants. The results obtained from carefully manipulated experiments, making use of these distance reactions, constitute proof of the presence and activity of sexual hormones. These results will be embodied in a second paper of this series soon to appear.

SEQUENCE AND TIME INTERVALS OF STAGES IN THE SEXUAL REACTION.—A hormonal coordinating mechanism is strongly indicated by the sequence of events in the sexual reaction and the time intervals at which they occur. Characteristic differences in the time intervals of the events in agar and water matings necessitate the consideration of each in some detail.

(a) Sequence and time intervals—in agar matings.—The course of developments in the sexual reaction can easily be followed when compatible & and P plants are mated on a suitable agar medium in Petri dishes. The medium best suited for this purpose was found to be one containing 0.3 per cent soluble starch, 0.1 per cent peptone, 1.0 per cent lentil (hot water extract), 2.0 per cent agar, and trace quantities of KH2PO4, MgSO4, CaCl2, FeCl<sub>3</sub>, and ZnSO<sub>4</sub>. Each plate was inoculated with the two sexually opposed strains, the inocula being placed at some distance so that the two resulting mycelia would occupy the greater part of the plate before contact occurred. This allowed for a long line of intermingling of the hyphae of the two plants. By inverting the plates and examining them with a dissecting or compound microscope, the matings could be observed without exposure to air-borne contaminants.

When compatible & and & plants are mated on lentil-extract agar, the first indication of a sexual reaction is the formation of antheridial branches near the tips of the & hyphae (stage one described above). For a period of 6-10 hours the only change to be seen is an increase in the number and length of these 3 branches, but after this period the 2 hyphae located nearest the activated portion of the & mycelium begin to produce oogonial initials at their tips or on short lateral branches (stage two). The time interval between the appearance of the antheridial branches and the oogonial initials indicates the diffusion of a substance from the & mycelium to the  $\mathcal{P}$ , initiating the production of oogonial initials. That oogonial initials are formed only after production of antheridial hyphae suggests the probability that such a substance is produced by the antheridial branches.

Beginning at the time the oogonial initial reaches its maximum size, 6–8 hours after its initiation, antheridial hyphae begin to grow directly toward it (stage three), and this directional growth continues for as long a period as 10–12 hours. After this period the oogonial initial exerts no influence over the growth of the antheridial hyphae, growth again occurring at random or toward other oogonial initials which are in the receptive stage. These facts indicate that a specific substance is produced by the oogonial initial for a period of approximately 12 hours after it reaches maximal size and that this substance is responsible for directional growth of the antheridial hyphae.

Once the tips of the antheridial hyphae have become applied to the wall of the organial initial, the delimitation of antheridia takes place (stage four), and it is only after a period of 2-4 hours after this

formation of the basal wall in the antheridium that the oogonium is likewise delimited from its stalk and parent ? hypha (stage five). The constancy of this time lapse is significant, and suggests that some substance is produced by the antheridium, after its delimitation, which is necessary before the oogonial initial is capable of becoming transformed into an oogonium.

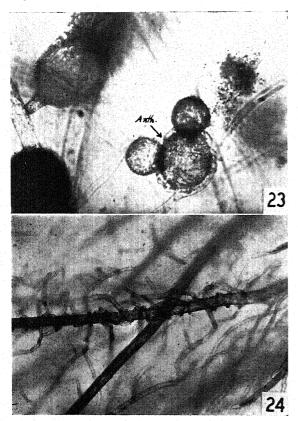

Fig. 23–24. Inter-specific matings of Achlya ambisexualis with A. bisexualis.—Fig. 23. Sexual reaction in inter-specific matings of Achlya ambisexualis  $Q \times A$ . bisexualis A. Numerous antheridial hyphae are applied to each oogonial initial (as shown at anth.) but neither antheridia nor oogonia are delimited.  $\times 100$ .—Fig. 24. A. ambisexualis  $A \times A$ . bisexualis  $A \times A$ . Disexualis  $A \times A$ . Disexualis  $A \times A$ . Disexualis  $A \times A$ . These are attracted to and become coiled around the vegetative hyphae of the  $A \times A$ . Usually no further reaction in either thallus.  $A \times A$ .

(b) Sequence and time intervals—in water matings.—The same sequence of events and the same proportionate time intervals are seen in water matings. These matings are made by bringing together vegetatively mature mycelia, growing on hemp seed, as described by Raper (1936).

In water matings of the same plants used for the preceding observations, the time intervals may be considerably shorter, antheridial branches appearing within two hours of the time that the pairings were made. This interval occurring between the time

that the two plants are placed in juxtaposition and the time of the appearance of the antheridial hyphae indicates that for the formation of the  $\delta$  initials some substance produced by the vegetative P plant is necessary. Thus the activity of the P in initiating the entire sexual process is suggested.

Beginning about 2 hours after the appearance of antheridial branches, oogonial initials start to appear along the line of intermingling of the two opposed mycelia. These enlarge rapidly and are soon producing the substance which attracts the antheridial branches. Finally, antheridial delimitation and oogonial delimitation occur in sequence soon after the ô initials reach the Q organ. In a mating of strongly compatible plants this entire process may be accomplished as soon as 8 hours after the plants are placed in contact. The time intervals, however, are proportionately the same as recorded for the process in agar medium, and the speed of the reaction can be attributed to the relatively greater ease of movement of substances in water by currents than in agar through diffusion alone.

It is also significant that under both cultural conditions no change in the sequence of events has ever been observed.

Incompatibility in interspecific matings of a. ambisexualis and a. bisexualis.—Incompatibility with failure of gametic union in the reciprocal matings between A. bisexualis and A. ambisexualis furnishes additional evidence for the hormonal mechanism. The sexual reaction never proceeds to completion in either of the two matings; the points at which the reaction stops in the two instances indicate definite specificity of two of the hormones involved.

In matings of A. ambisexualis  $\mathcal{P} \times A$ . bisexualis ô incompatibility appears to be due to a failure of the agent which brings about the delimitation of the antheridium in a normal mating. It has been repeatedly seen that when this mating is made in agar or in water the first three stages of the sexual reaction occurs as in matings of perfectly compatible strains. The production of antheridial hyphae on the ô plant, the subsequent formation of oogonial initials on the 9, and the attraction of the antheridial hyphae to the oogonial initials are all normal. At this point, however, the coordinating mechanism breaks down and no antheridia are delimited, although the 3 initials are wrapped around the 9 organs (fig. 23). This suggests specificity of some substance produced by the oogonial initial which is necessary for the delimitation of the antheridium. It will be shown in the second paper of this series that this is the case, and this reaction to a specific substance is coupled with a thigmotropic response of the antheridial hyphal tip to solid substances.

This reaction further supports the concept that a substance, produced by the antheridium, is effective in the differentiation of the oogonium. For here, although the antheridial branches are applied to the wall of the oogonial initial as in normal reproduction, subsequent development of the  $\mathfrak{P}$  sexual organs

fails to occur. If the delimitation of the oogonium were simply a thigmotropic response to the presence of antheridial hyphae applied to its wall, this differentiation would take place. Apparently a substance produced by the antheridium in contact with the oogonial initial is necessary for the delimitation of the latter.

Incompatibility is again seen in the reciprocal mating, A. ambisexualis  $\delta \times A$ . bisexualis  $\circ$ . This reaction, however, differs markedly from that observed in the preceding mating. Antheridial branches are produced in profusion on the & hyphae, but there is no reaction in the  $\mathcal{P}$  in response to the extensive production of these organs and, presumably, the secretion of a large amount of the substance which normally would bring about the formation of oogonial initials. In water matings of these two plants antheridial hyphae are attracted to the vegetative hyphae of the 2 and become intricately entwined about these filaments (fig. 24). There is no reaction in the female except for the production of structures which at first appear to be oogonial initials but which later become differentiated not as oogonia, but as "resistant spores." These resistant spores were first described by Weston (1917) and have since been shown by the writer (1936) to be resistant vegetative structures characteristic of the  $\circ$  strains of A. bisexualis. The number of these spherical bodies is increased by the presence of the partially compatible 3 plant, and in such a mating they are occasionally produced on lateral branches, while in single culture they are borne only in a terminal position on the vegetative hyphae.

When this interspecific mating is made on agar, the reaction is the same as in water except for one significant difference. The directional growth of antheridial branches toward the vegetative hyphae of the  $\mathfrak P$  and the characteristic twining around the  $\mathfrak P$  hyphae occur only near the surface of the agar, presumably where a supply of oxygen is available. The formation of antheridial branches, however, is not limited to this region, approximately the same quantity being produced at all levels in the substrate.

The production of antheridial branches by the  $\delta$  indicates that the primary specific substance of A. bisexualis  $\mathfrak P$  is capable of bringing about the same specific reaction caused by the primary substance of A. ambisexualis  $\mathfrak P$ . The attraction of the antheridial branches to the vegetative hyphae of the  $\mathfrak P$  indicates further that this substance is also effective in causing directional growth of the antheridial hyphae, which is normally (i.e., in compatible matings) controlled by a substance diffusing from the oogonial initial. The antheridial branches do not respond further by the delimitation of antheridia as in the presence of oogonial initials of a  $\mathfrak P$  plant of the same species.

Analysis of the incomplete sexual reactions between A. ambisexualis and A. bisexualis indicates that high specificity of certain of the sexual hormones is responsible for the failure of the process. The logical conclusion to draw from these observations is that complete incompatibility would result when the  $\delta$  is incapable of responding to the primary substance secreted by the vegetative mycelium of the  $\mathfrak{P}$ .

Effects of variations in the composition of the medium.—In an attempt to determine the range of substances necessary for the accomplishment of the sexual process, matings of  $\delta$  and P plants have

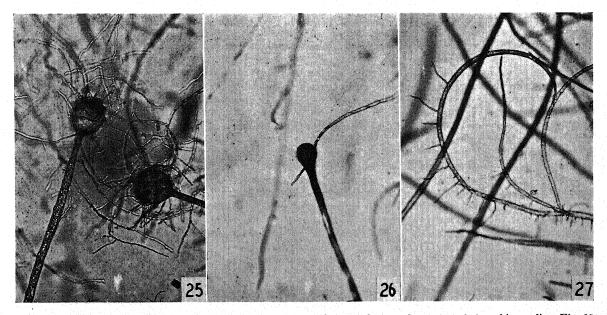

Fig. 25-27. Effects of variations in the composition of the medium on the sexual reaction of A. ambisexualis.—Fig. 25. Insufficient quantity of Fe+++ results in failure of oogonial delimitation.  $\times 80$ .—Fig. 26. PO<sub>4</sub>--- deficiency results in failure of attraction of antheridial branches to oogonial initials.  $\times 40$ .—Fig. 27. Certain nutritional conditions cause failure of sexual reaction at completion of first stage.  $\times 40$ .

been carried out on a large number of agar media. While these experiments have not given the results hoped for, certain facts have been observed which support the concept of coordination by hormones in the sexual process. By manipulating the composition of the semi-solid substrate on which the plants were mated, it has been found that until the time of oogonial delimitation the sexual reaction can be stopped at any desired point.

When the amount of iron in the medium is decreased, a significant effect on the reproductive process is brought about. The reaction is at first normal, antheridial hyphae being produced in large numbers. The second stage of the reaction, the formation of oogonial initials, follows as in an ordinary mating. The third and fourth stages, attraction of antheridial hyphae to the oogonial initials and subsequent delimitation of antheridia, occur in the typical order and manner. At this point the reaction stops, the oogonial initial failing to form a basal wall to delimit the  $\mathcal{P}$  gametangium (fig. 25).

To explain this phenomenon two possibilities are suggested: (1) that a certain amount of iron, which is here present in insufficient concentration, is needed by the antheridium for the elaboration of the oogonial delimiting agent, (2) that a greater concentration of iron than is present is required by the oogonial initial before a basal wall can be formed.

A second similar effect is seen when the amount of phosphate in the medium is decreased. Ordinarily KH<sub>2</sub>PO<sub>4</sub>, in concentration of M/30,000, is added to the medium, but here this salt is omitted, potassium being furnished in equal amount as KCl. Of course phosphate is present in the starch which is used as a carbohydrate source, but the omission of the amount which is normally added causes interesting and significant changes in the sexual reaction. The initial reaction is normal with the production of large numbers of antheridial hyphae by the 3 mycelium. The next stage is also apparently normal, for oogonial initials are formed in considerable quantity. At this point, however, the coordination of the sexual processes is interrupted, for the antheridial branches are not attracted to the oogonial initials. Figure 26 presents this phenomenon well, for it shows an antheridial branch which touches an oogonial initial, avoids it, and continues growing, an event which has never been seen in a normal mating. This suggests that phosphate in greater concentration is necessary for the normal reaction brought about by a substance secreted by the oogonial initial. Again, as in the preceding case, no evidence is present to indicate whether this effect depends on the production or the utilization of the substance. The experiment, however, gives supporting evidence for the attraction of the antheridial branches to the oogonial initial by a substance secreted by the ? initial itself rather than a second response to a substance produced at all times by the 2 mycelium.

The disruption of the sexual process at the end of the first & reaction has also been observed. Of a large number of media tried three were found which would support more or less vigorous growth but on which the only reaction between the two mycelia was the production of antheridial branches. No further development was seen in either 3 or 2. These media, prepared with Pyrex distilled water containing low concentrations of various salts (KH<sub>2</sub>PO<sub>4</sub>, M/3×10<sup>4</sup>; MgSO<sub>4</sub>, M/8×10<sup>4</sup>; CaCl<sub>2</sub>, M/10<sup>5</sup>; FeCl<sub>3</sub>, M/10<sup>6</sup>; and ZnSO<sub>4</sub>, M/10<sup>7</sup>), are as follows:

- 1. Cysteine-HCl
   .0.05%
   2. Starch
   .0.3%

   Sodium Butyrate
   0.05%
   i-Inositol
   .0.1%

   i-Inositol
   .0.05%
   Glycine
   .0.05%

   Agar
   .2.0%
   K<sub>2</sub>S
   Trace

   Agar
   .2.0%

   Water
   Water

In media 2 and 3,  $K_2S$  and cysteine-HCl were added to provide utilizable sulfur, these plants as shown by Volkonsky (1933) being incapable of reducing the sulphate radical.

Å few media were tested which were apparently unable to support the sexual reaction in any of its stages. On a medium composed of 0.3 per cent starch, 0.1 per cent i-inositol, 0.1 per cent cysteine-HCl, 2.0 per cent agar, and the salts listed above, the reaction is normal, a large number of mature sexual organs and fertilized eggs being formed. In media having cystine or methionine substituted for the cysteine-HCl in the above formula, vigorous and healthy growth of the mycelia occurs, but there is no reaction between the ♂ and ♀ plants.

Since compatible mycelia have always been observed to give a strong normal sexual reaction in lentil-extract agar, this medium has been used as a control in all these experiments. Lentils are known to contain two substances often shown to be nutritional requirements for a number of plants: vitamin  $B_1$  and inositol. Of these, vitamin  $B_1$ , when added to various media, causes no appreciable change in the vigor of either growth or sexual reactions of the plants. This differs from the condition found in Phycomyces Blakesleeanus by Schopfer (1931), who showed that the addition of this vitamin increased the intensity of the sexual reaction between (-) and (+) strains of that species. The possibility of the reaction being influenced by the other growth component, inositol, has likewise been investigated, but the results are not unquestionably definite.

Hydrogen-ion concentration was early suspected of being an important factor in the reproductive process. To test this possibility  $\delta$  and  $\mathfrak P$  plants were mated on a series of starch-peptone-inositol agars adjusted to pH values of 3.7, 4.5, 5.0, 5.5, 6.0, 7.0, and 7.5 by means of potassium phosphate buffers (M/150, total phosphates). Growth was equally vigorous in all cases; similarly, formation and matura-

tion of sexual organs did not vary appreciably at the different levels of hydrogen-ion concentration.

THE HORMONAL MECHANISM.—From the different lines of evidence presented above it is obvious that a well-developed mechanism is operative in initiating and coordinating the different stages of the sexual process in matings of ô and ♀ plants of Achlya ambisexualis and A. bisexualis. The sequence of the events in the process and the time intervals at which they take place indicate that this coordinating mechanism involves diffusible substances, and the pattern of incompatibility in interspecific matings between these two species as well as the manner of disruption of the process by changes in the composition of the medium indicates that these substances are four in number and that they are characterized by a certain degree of specificity. Furthermore, this body of evidence points to the probability that the sexual reaction in both these species is under hormonal control, at least until the time of the delimitation of the oogo-

During the time which elapses between the approximation of the  $\delta$  and  $\mathfrak P$  mycelia and the formation of the basal wall of the oogonium, two substances are produced by the  $\mathfrak P$  which bring about specific responses in the  $\delta$ , and two are produced by the  $\delta$  which induce specific reactions in the  $\mathfrak P$ . These hormones, the points of their origins, and their specific activities have been reported in a preliminary note (Raper, 1939) from which table 1 is taken.

The reactions brought about by these hormones constitute a chained reaction with each of the different stages in the reproductive process being dependent on the preceding ones.

The rôle of these hormones as coordinators in this process can easily be seen. Hormone A is the only one of these substances which is not produced by specialized and localized organs. It is apparently secreted at all times by the vegetative mycelium of the female. Antheridial branches are produced only in response to the presence of hormone A. The ô initials thus formed, in turn, produce a second specific substance, hormone B, which is required for the next stage of the sexual reaction—namely, the formation of oogonial initials. The oogonial initials, once they reach maturity, produce a third substance, hormone

C, which has two functions: (1) causing directional growth of the antheridial branches toward the point of its production, the  $\,^{\circ}$  initials, and (2) bringing about the delimitation of antheridia at the tips of the antheridial branches once they are applied to the walls of the oogonial initials. Finally, a fourth substance, hormone D, is secreted only by the delimited antheridium, and it brings about the formation of a basal wall which separates the oogonium from the parent  $\,^{\circ}$  hypha.

In the normal course of events in matings, either in water or in a semi-solid substrate, this mechanism of hormonal coordination induces the formation of the various sexual organs only when they may be most effective. In certain cases, however, as shown in the inter-specific matings and the nutritional experiments, it is possible to bring about the breakdown of the system with consequent decrease, or complete failure, in gametic union and the production of fertilized eggs.

The term "hormones" is here applied to the specific sexual substances of *Achlya* in accord with Huxley's (1935) classification of hormones.

Hormones were first defined by Bayliss and Starling (1904) as substances which, being produced in one part of the animal body, are carried by the blood stream to another part where they bring about a specific physiological reaction. In their monograph, Phytohormones, Went and Thimann (1937) revised this definition to include the auxins, defining a hormone as a chemical substance which, being produced in one part of an organism, is transported to another where its activity is manifested. It was pointed out logically enough by Huxley that whether or not a chemical substance is a hormone should depend on its activity rather than the mechanical mode of its transportation. His classification separates hormones into two groups: A, "regional activators" and B, "distance activators." In the second group he places those substances, which, transported by diffusion within the body of a single organism or between different individuals, bring about specific responses. In this category would belong the first three substances defined above, while the fourth, hormone D, which is not diffusible through long distances,

TABLE 1.

Hormone	Produced by	Affecting	Specific action(s)
A	Q-Vegetative hyphae	∂-Vegetative hyphae	Induces formation of antheridial branches
В	&-Antheridial branches	Q -Vegetative hyphae	Initiates the formation of oogonial initials
c	Q-Oogonial initials	3-Antheridial branches	<ol> <li>Attracts antheridial branches</li> <li>Induces, in connection with a thigmotropic response, the delimitation of antheridia</li> </ol>
D	∂-Antheridia	♀-Oogonial initials	Brings about the delimitation of the oogonium by the formation of a basal wall

[Vol. 26.

could perhaps best be included in the group, "chemical differentiators" of the "regional activators."

### SUMMARY

During the course of an investigation of the sexuality in Achlya, a new species was found and is here described as A. ambisexualis. Ten isolates of this plant, collected by the writer, are separated on the basis of morphology of vegetative mycelium and sexual organs into three varieties: type, var. abjointa, and var. gracilis. The sexuality of the plant agrees with that of other partially separate-sexed species of the watermolds which have been described as heterothallic.

The successive stages in the sexual reaction of A. ambisexualis and A. bisexualis are described in detail. Until the time of P gametangial differentiation, five stages are recognized: (1) production of antheridial hyphae on P mycelium, (2) formation of oogonial initials on P, (3) directional growth of antheridial branches to P initials and the application of the tips of the P initials to the wall of the P organ, (4) the delimitation of antheridia at the tips of the

antheridial branches in contact with the  $\varphi$  initial wall, and (5) the formation of a basal wall delimiting the oogonium from the parent  $\varphi$  hypha.

The rigid sequence of events and the constantly proportionate time intervals between these stages indicate a well developed coordinating mechanism.

Incompatibility in inter-specific matings between A. ambisexualis and A. bisexualis is apparently the result of interruptions in the coordinating mechanism. The reaction differs in the two reciprocal matings.

By varying the chemical composition of the medium, disruption of the sexual process at times coinciding with the initiation of the several stages indicates specific substances as the coordinating agents.

On the basis of these facts, a hormonal system is outlined. Four specific substances are involved: two from the  $\delta$  and two from the  $\varphi$ , each bringing about specific responses in the activity of the opposed mycelium.

# THE SIGNIFICANCE OF WOOD ANATOMY IN THE TAXONOMY OF THE JUGLANDACEAE <sup>1</sup>

Charles Heimsch, Jr., and Ralph H. Wetmore

Manning (1938a) has recently made a comparative morphological investigation of inflorescences of the various members of the Juglandaceae. He finds that the inflorescences of the family are based on a fundamental pattern though showing varying degrees of reduction along certain definite lines from a primitive type. This primitive type is a terminal androgynous panicle consisting of a central pistillate catkin surrounded by several staminate branches or catkins. In Manning's opinion, the genera Alfaroa, Engelhardtia, and Platycarya exhibit this primitive type, whereas the genera Juglans, Carya, and Pterocarya possess specialized or derived types of inflorescences. His conclusions were founded on morphological rather than anatomical considerations.

That studies of the secondary xylem in the dicotyledons may aid the phylogenist in his attempts to establish natural relationships among certain families of Angiosperms has been shown by Vestal (1937), Tippo (1938), and Taylor (1938), students from these laboratories. In these investigations involving taxonomic groupings of families attempts were made to correlate xylem structure with existing systems of classification, and their findings indicate an interestingly high degree of correlation between the two. So much is this the case that groups which fail to show this correlation are suspected of being erroneously placed in the system being examined.

Bailey and his students have established certain lines of structural specialization in dicotyledonous xylem. Bailey and Tupper (1918) obtained significant data regarding the classification and length of vascular elements. Frost (1930a, 1930b, 1931), by statistical methods, after a survey involving the majority of the dicotyledonous families, revealed the trends of specialization of the vessel segment. Using Frost's results as a basis, Kribs (1935) found a high degree of statistical correlation between the type of wood rays and the degree of specialization in the vessel segment. By use of similar methods, Kribs (1937) correlated vertical parenchyma patterns with primitive and advanced types of vessel members.

Although the previous attempts to use these anatomical tools have had as their central theme the determination of relative positions of families in natural taxonomic groupings, evidence was also obtained that these anatomical principles would apply equally well to considerations within the specific family, providing a significant range of structural variability exists in the family.

A detailed description of the anatomy of the secondary xylem of the Juglandaceae was published by Kribs in 1927, based on the limited material available to him. With these lines of specialization in mind, and a fairly complete representation of the genera with which to work, the present investigation was undertaken in order to determine to what extent the findings based on xylem anatomy of the Juglandaceae would accord with those obtained from a study of the organization of the inflorescences.

MATERIALS AND METHODS.—For this investigation the microscopic slides, the dried, and the preserved wood in the Harvard Collection were at the writers' disposal. Through the courtesy of Professor Samuel J. Record of the Yale School of Forestry, additional specimens were obtained. Material was also collected from members of the family growing in the Arnold Arboretum.

Before additional slides were made, it was found necessary to soften the material in hydrofluoric acid. When embedding was necessary, celloidin was used, following the standard technique of Wetmore (1932). The living material was fixed in formacetic-alcohol, washed in tap water, softened and embedded. Sections 10 micra thick were made, stained with safranin and Heidenhain's iron-alumhaematoxylin, and mounted permanently in Canada balsam or diaphane.

Macerations were made of representative material of all the genera, using equal amounts of 10 per cent chromic and 10 per cent nitric acids at a temperature of 60°C. for 48 hours. Following thorough washing, the separated elements were stained with water-soluble nigrosine and dehydrated in rapidly increasing percentages of ethyl alcohol. Permanent mounts were made using diaphane as a mounting medium.

Preliminary examinations showed that when 50 measurements of the vessel member lengths and of fiber-tracheid lengths were used, these followed the normal curve of distribution; thus, this number of length measurements was averaged for the respective elements for each species. From these the averages for the genera were derived. For vessel diameters 25 random measurements were averaged for each species represented, except for those species which were ring-porous or tended toward ring-porosity, then only the larger pores were measured.

The values for the angle of the end wall were obtained by taking 10 random measurements of each species with a camera-lucida. These were averaged, and from these the averages for the genera were computed. Preliminary figures concerning ray height were not significant, and this can be attributed to ontogenetic changes in the form and character of the wood rays. With increased knowledge concerning the ontogeny of the various types of wood rays, statistical treatment of the characters may prove to be significant.

All photographs were taken on DC Ortho plates with Zeiss lenses and Zeiss photomicrographic equipment.

<sup>&</sup>lt;sup>1</sup> Received for publication June 19, 1939.

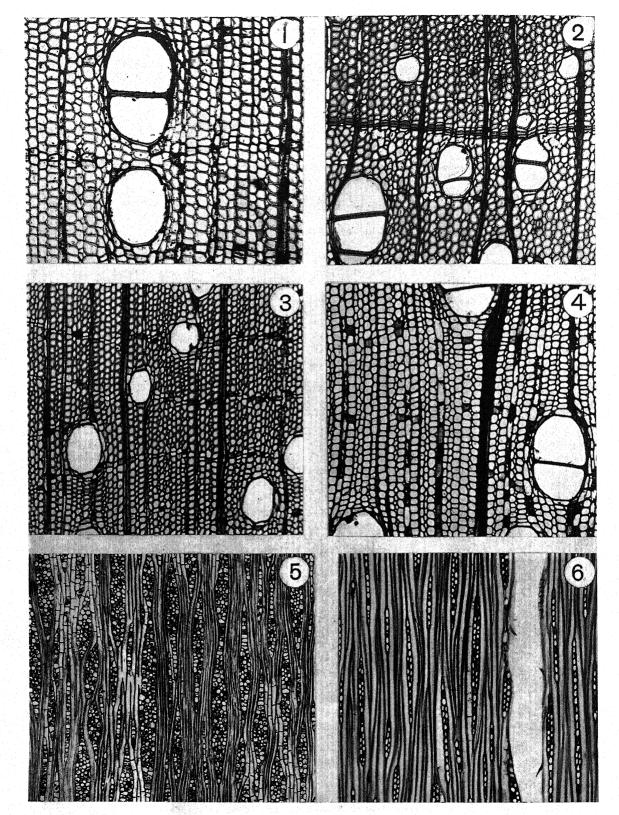

Fig. 1-6.—Fig. 1. Alfaroa costaricensis Standl. Transverse section showing thin-walled fiber-tracheids, thin-walled angular to round pores, and banded apo-paratracheal parenchyma. ×155.—Fig. 2. Pterocarya Paliurus Bat. Trans-

Anatomical description of the genera.—Alfaroa (fig. 1, 8, 11, 13).—The one species, A. costaricensis Standl., is native to Central American highlands. Growth rings are present. The main ground mass of imperforate cells consists of thin-walled fiber-tracheids; as might be expected, these fibertracheids of the late wood become progressively thicker walled. Arcs of gelatinous fibers are present in the twigs. Vessel pores are chiefly solitary or in radial multiples of 2-6 with a few clusters and short chains (fig. 1). The wood is definitely diffuse-porous. The vessels are thin-walled with angular to rounded outlines and possess a few thin-walled tyloses. Vessel perforations may be either scalariform or porous with a higher percentage of the scalariform type than elsewhere in the family (fig. 8). The bars range from one to twelve or more in number, and the apertures are completely bordered.

Intervascular pitting is circular-bordered and alternate (fig. 8), a feature in distinct contrast to the predominate gash-like vessel-ray (fig. 11) and vessel-parenchyma pitting. The rays are heterogeneous I (Kribs, 1935), and the multiseriate portions of the multiseriate rays are from 2-3 cells wide (fig. 13). Parenchyma occurs in fine concentric bands, one to two cells in width. There is also scanty vasicentric and terminal parenchyma. Although the parenchyma is not concentrated about the vessels, one or more vessels are infrequently contacted by the bands in their tangential extension. This places the parenchyma pattern intermediate between distinct apotracheal and distinct paratracheal types (Chalk, 1937), which fact seems to justify the use of the term apoparatracheal in describing the parenchyma pattern occurring here. Rays frequently contain small crys-

Engelhardtia (fig. 3, 4, 9, 10, 12).—The genus consists of 11 species from southeastern Asia, Mexico, and Central America. Of the 8 species investigated, only two, E. Fenzellii Merrill² and E. pterocarpa Standl.,³ show definite growth rings. However, the other specimens give evidence of a periodic slowing down in growth processes in the form of thickened fibers, but no definite rings are present. The imperforate tracheary elements are of the fiber-tracheid category with slightly thicker walls than those of Alfaroa. Gelatinous fibers occur in E. pterocarpa. Though vessels are predominately either solitary or in radial multiples, the relative percent-

<sup>2</sup> Manning (1938a) indicates that *E. chrysolepis* Hance, *E. Fenzellii* Merrill, and *E. formosana* Hayata are synonyms.

<sup>3</sup> Standley (1927) suggests that *E. pterocarpa* Standley and *E. Oreomunnea* C. DC. are synonyms.

age of each may vary considerably. Invariably a few pore clusters are present. All species are diffuse-porous. Vessels are angular to round in outline, with the tendency toward roundness more pronounced in some species (fig. 3, 4). Vessel walls are thin, and thin-walled tyloses were present in about half of the species.

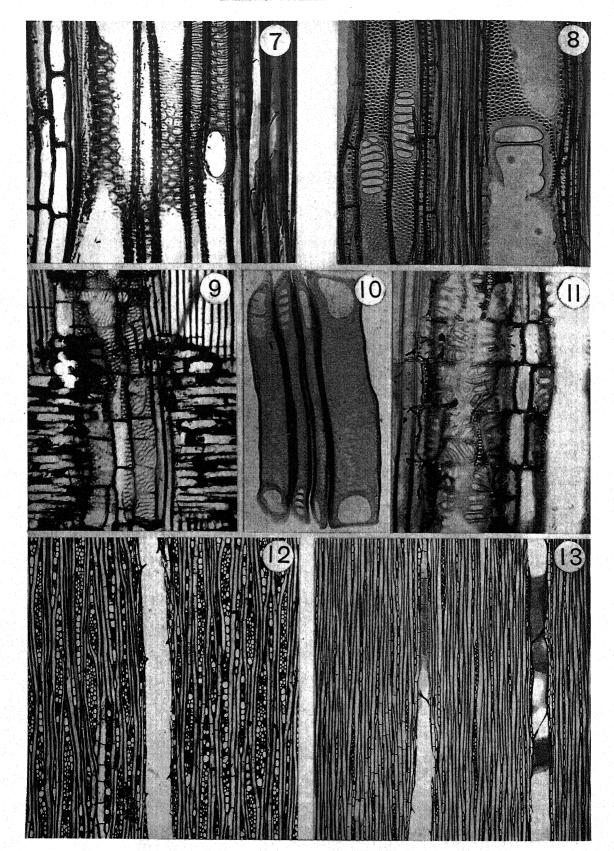

Vessel perforations are either scalariform or porous (fig. 10). The scalariform perforations occur chiefly in the smaller segments and are found in all species. The bars range from one to nine or more in number, and, contrary to Kribs' statement (1927), there is no distinction between the American and the Asiatic species in this regard.

Intervascular pitting is circular-bordered and alternate. Vessel-ray and vessel-parenchyma pitting varies from small half-bordered pit-pairs in certain species to small half-bordered and gash-like pit-pairs in other species (fig. 9). Similarly the rays vary from heterogeneous IIA in some species to heterogeneous IIB in others, with some species transitional between the two ray types (fig. 12). Multiseriate rays are from 2-4 cells wide.

E. spicata Blume has diffuse, diffuse-in-aggregates, banded apotracheal and scanty vasicentric wood parenchyma (fig. 4). The pattern is irregular with the emphasis on diffuse-in-aggregates and scanty vasicentric. E. spicata Blume, var. aceriflora Koord. and Valet. has a more regular parenchyma pattern with the narrow apotracheal banded condition more pronounced; however, the diffuse-inaggregate condition is present. These descriptions are in general agreement with those of Janssonius (1936) for the above species. In the remaining species, the apo-paratracheal banded condition predominates (fig. 3). There is, in addition, a tendency for the parenchyma to be irregularly clustered about the vessels, forming caps, with the narrow bands extending laterally from these. Diagonal connections between some bands occur. In all species except E. chrysolepis and E. Fenzellii some parenchyma exists in diffuse aggregates. Those species with growth rings possess terminal parenchyma. Crystals were found in the vertical parenchyma of E. formosana, E. pterocarpa, and E. Oreomunnea.

Pterocarya (fig. 2, 6).—The genus is comprised of 8-9 species; these are found in Trans-Caucasia, China, and Japan. Of the 5 species investigated, all showed growth rings. Imperforate tracheary elements are thin-walled fiber-tracheids except at the terminus of each growth ring where a narrow band of thick-walled elements occurs (fig. 2). Twigs of P. stenoptera C. DC. and P. hupehensis Skan. show gelatinous fibers. Vessel pores are chiefly solitary or

verse section showing growth ring; fiber-tracheids with slightly thickened walls (thick walled in late wood); thin-walled, angular to round pores; banded apo-paratracheal parenchyma, and terminal parenchyma. ×92.—Fig. 3. Engelhardtia Fenzellii Merr. Transverse section showing fiber-tracheids with slightly thickened walls; thin-walled, angular to round pores; and banded apo-paratracheal parenchyma. ×92.—Fig. 4. Engelhardtia spicata Bl. Transverse section showing distribution of elements, particularly diffuse, diffuse-in-aggregate, and scanty vasicentric vertical wood parenchyma. ×92.—Fig. 5. Platycarya strobilacea Sieb. and Zucc. Tangential section showing wood rays, vertical parenchyma, and small vessels associated with vasicentric tracheids. ×48.—Fig. 6. Pterocarya stenoptera C. DC. Tangential section showing nearly homogeneous rays. ×92.

in short radial multiples with a few clusters. All species are distinctly diffuse-porous except P. Paliurus Bat. which tends to be ring-porous. Vessels of P. stenoptera C. DC. are angular in outline, all others angular to round. All vessels are thin-walled and a few thin-walled tyloses are present.

Vessel perforations are all porous, and intervascular pitting is alternate. Vessel-ray and vessel-parenchyma pitting consists of small half-bordered pitpairs. Rays are heterogeneous IIB, and the multiseriate rays are from 2-4 cells wide (fig. 6). Parenchyma is of apo-paratracheal bands, mostly onecell wide, these bands being quite regular (fig. 2). Accompanying this pattern is scanty vasicentric pa-

renchyma in all species.

Juglans (fig. 14, 17, 19).—The existing species of Juglans are found in China, Japan, India, Persia, United States, Mexico, Central America, West Indies, and the Andean region of South America from Colombia and Venezuela to Argentina. Of the 14 species investigated, J. pyriformis Liebm. from Salvador showed no growth rings, and J. insularis Griseb. from Cuba showed them only faintly. All other specimens possess distinct growth rings. The imperforate tracheary cells are all fiber-tracheids. As Kribs indicates (1927), J. cinerea L. (fig. 19), J. mandschurica Maxim., and J. Sieboldiana Maxim. tend to have vascular elements with thinner walls than those of the remaining species (fig. 14, 17). As in Pterocarya, the growth rings are terminated by narrow bands of elements with thickened walls (fig. 19). A few species show gelatinous fibers.

Vessel distribution follows that of the previously described genera with emphasis on the solitary and multiple arrangements with occasional clusters. In general the genus is diffuse-porous, but its members exhibit a distinct tendency toward ring-porosity. In most cases there is a gradual diminution of vessel diameter from the early to the late wood of a season's growth. The vessels possess angular to rounded outlines with a greater tendency toward roundness than was present in the above genera. Vessel walls are thin; those forms which have thinner-walled fibertracheids likewise have vessels with thinner walls. Tyloses are generally present, varying from few to many; in all cases they are thin-walled.

Vessel perforations are strictly porous, and intervascular pitting is uniformly circular bordered and alternate. Vessel-ray and vessel-parenchyma pitpairs are small and half-bordered. Rays are generally heterogeneous IIB, but in J. nigra L. and J. Sieboldiana they closely approximate homogeneity. Multiseriate rays range from 2-5 cells in width.

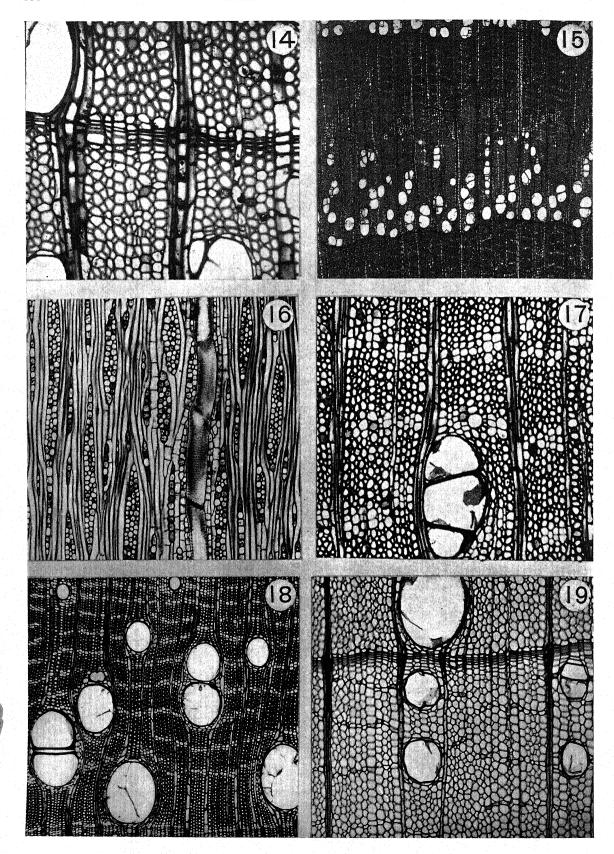

In all but three species there is some parenchyma that is diffuse or diffuse-in-aggregates. In J. californica S. Wats., J. mandschurica, J. nigra, and J. rupestris Engelm. the above parenchyma patterns predominate (fig. 14). In these cases there is always a variable amount of vasicentric parenchyma present. In most of the species there is a definite banding of the parenchyma; in J. australis Griseb., J. boliviana Dode, and J. Sieboldiana, the banding is more independent of the vessels than in J. cinerea, J. colombianensis Dode, J. insularis, J. neotropica Diels, and J. pyriformis Liebm. (fig. 17). Because of the association with the vessels in these latter species, it seems that the bands can most properly be called apo-paratracheal. Terminal parenchyma is present in all species with growth rings (fig. 19). Crystalliferous parenchyma strands are present in most of the species.

Carya (fig. 16, 18, 20, 21).—The 18 or 19 species of this genus are found from Canada to Mexico in the eastern half of the United States, with one species in China, and one species in Indo-China. All the species investigated show growth rings. Imperforate tracheary elements are fiber-tracheids, but in some cases the pit borders are exceedingly minute. Gelatinous fibers are present in a few species. Pores are chiefly solitary and in radial multiples of 2-4 with occasional short chains and clusters. All species are distinctly ring-porous (fig. 18), although C. tonkinensis Lecomte, an Asiatic species, does not show the extreme size difference between the vessels of the early and late wood that are found in the American species (fig. 21). Vessel outlines are exclusively round, and the walls are thickened over the vessel walls of the previously described genera (fig. 18). Especially prominent in this regard are the extremely thickened walls of the small late-formed vessels in the seasonal growths. Numerous thinwalled tyloses are characteristic of the genus, and they occur almost entirely in the large vessels.

Vessel perforations are exclusively porous, and intervascular pitting is crowded and alternate. Vessel-ray and vessel-parenchyma pitting consists of small half-bordered pit-pairs. Rays are heterogeneous IIB (fig. 16). As Kribs states (1928), those of C. tonkinensis are more heterogeneous than those of the American species (fig. 20). The multiseriate rays range from 2-5 cells in width.

Generally, in Carya, the parenchyma is distinctly banded, the bands being apo-paratracheal and associated with vasicentric parenchyma in varying amounts (fig. 18, 21). However, most species show some diffuse and diffuse-in-aggregate parenchyma

Fig. 7-13.—Fig. 7. Platycarya strobilacea Sieb. and Zucc. Radial section showing porous perforation plate and vessels and vasicentric tracheids with spiral thickenings. ×285.—Fig. 8. in the spring wood. Crystals occur in swollen parenchyma cells, being most abundant in *C. tonkinensis* (fig. 20, 21).

Platycarya (fig. 5, 7, 15).—P. strobilacea Sieb. and Zucc., the one species, is confined to China and Japan. The wood shows well-defined growth rings (fig. 15). Fiber-tracheids compose the greater part of the wood, and those of the late wood have thickened walls over those of the early wood. Gelatinous fibers are also present. The wood is ring-porous. Large vessels are solitary, in short radial multiples, chains or clusters, whereas the smaller vessels and the vascular tracheids with which they are associated are in a flamelike arrangement. These small vessels and the vascular tracheids have spiral thickenings in the secondary walls (fig. 7). Large vessels have moderately thickened walls and tend to be round in outline. Small vessels are thinner-walled and angular. A few thin-walled tyloses are present in the large vessels.

Vessel perforations are exclusively porous. Intervascular pitting is alternate, and vessel-ray and vessel-parenchyma pitting consists of small half-bordered pit-pairs. Rays are heterogeneous IIB, and the multiseriate rays are often very high (fig. 5). Likewise relatively long uniseriate tips of more or less upright cells are common to the multiseriate rays. The multiseriate rays range from 2-8 cells in

width, thus they are the widest in the family. Sections of twigs near the pith indicate that these widths are the result of ontogenetic increase in cell numbers. Uniseriate rays are few in number and are from low to very high.

In the early wood, parenchyma is diffuse, diffuse-in-aggregates and scanty vasicentric (fig. 15). This gives way, in the late wood, to a banded apotracheal condition. It could not be properly determined whether or not terminal parenchyma was present, but from all indications it is. Rhomboid crystals occur in ray cells.

General descriptions it is evident that certain anatomical descriptions it is evident that certain anatomical characters are more or less constant throughout the family. Among these are the characteristic fibertracheids of the family. However, the thickness of the walls of these elements varies. Gelatinous fibers occur in every genus. Solitary pores with varying percentages of short radial multiples are the rule. Intervascular pitting is always alternate, and thinwalled tyloses are universally present.

In addition, the pattern of the wood parenchyma varies but little from genus to genus. Hyde (1925) and others have referred to tangential banding of parenchyma as being like that of the Juglandaceae. In each genus the banded nature of the parenchyma predominates, although variations from this pattern

do occur. A few species only show a preponderance of diffuse or diffuse-in-aggregate parenchyma. In practically every slide which shows growth rings terminal parenchyma<sup>4</sup> is a counterpart.

It is obvious that the several characters with limited variation contribute no evidence with reference to the anatomical specialization of the individual genera. Also it is noteworthy that the variation in certain characters is dependent upon the environment—i.e., diffuse-versus ring-porosity; and proper allowances for this fact need to be made in dealing with relative specializations. However, it will be seen that in the Juglandaceae these instances which merit special considerations do not detract from the general scheme of xylem organization and thus do not impose limitations upon ideas concerning the anatomical specialization of the genera.

It will be recalled that Manning ascribes a primitive type of inflorescence to the genera Alfaroa, Engelhardtia, and Platycarya. The thin-walled fibertracheids of Alfaroa are more primitive than those with thicker walls in the other genera. Diffuse-porosity is less advanced than is ring-porosity (Frost, 1930a). It is commonly accepted that the scalariform vessel perforation is more primitive than the porous perforation; thus, in this regard, Alfaroa is the most primitive genus of the family. In their thin walls and angular outlines, the vessels also reveal primitive characteristics. Likewise, the heterogeneous I type of ray present in the genus is the most primitive type of the family. Thus it is quite evident that the secondary xylem of Alfaroa is rather primitive. This is in direct agreement with the results of the inflorescence studies. Additional evidence for the primitive status of Alfaroa is brought forth by Manning (1938b) in that he relegates the stigmas to a low position when compared with those in the other genera of the family.

<sup>4</sup> Terminal parenchyma is defined in the Glossary of the Committee on Nomenclature of the International Association of Wood Anatomists (1933) as being "aggregated wood parenchyma forming a more or less continuous layer of variable width at the close of a season's growth." It appeared, however, in the majority of cases to be a part of the spring growth but on the face of the old growth ring. Chowdhury (1936) has suggested that such parenchyma be termed "initial parenchyma" rather than terminal.

Since these first formed elements in the spring growth are parenchymatous, it was thought that perhaps the septations in the fusiform daughter cells might occur in the fall with further differentiation delayed until spring. If this proved to be the case, the use of the term "terminal" would then be justified. Material of a few members of the family was collected in late November with considerable snow on the ground, and from all indications growth had ceased. Upon examination after sectioning, contradictory evidence was obtained. In Pterocarya Rehderiana C. K. Schneider, the majority of the cambial daughter cells, as well as cells which were wholly or partially differentiated, showed no cross walls. In Juglans cinerea, however, the majority of these late-formed elements showed septations. This only serves to indicate that specific differences as well as specific environmental responses may be involved. More material, collected at the proper time, must be investigated to determine which, if either, of these cases would hold true for the remainder of the family.

Engelhardtia as a genus agrees markedly with Alfaroa in its diffuse-porosity. Although the vessels tend to lose their angularity, they remain thinwalled. The fiber-tracheid walls are also relatively thin. In addition, scalariform vessel perforations are present, although they are less abundant than in Alfaroa. Manning (1938a) states that some species of Engelhardtia show considerable advance in inflorescence type and that (1938b) both primitive and advanced types of stigmas are present in the genus. This more or less harmonizes with the variation found in vessel perforation types. In this connection, a figure from E. Fenzellii is enlightening (fig. 10). The four vessels shown were four adjacent elements in the same radial row; and from the variation in the vessel perforations within this small number of chances, we are given some indication as to the rôle ontogenetic forces must play in the determination of the end product. Nevertheless, the tendency to produce the scalariform type of vessel perforation is present.

The rays of certain species, being heterogeneous IIA, are less highly organized than those of the remaining genera. Thus, Engelhardtia, as a genus, although on an average more specialized anatomically than Alfaroa, retains many primitive features. This fact parallels the conclusions of Manning.

Kribs comments on the fact that, on anatomical grounds, *Pterocarya* resembles the soft-wooded species of *Juglans*. The present investigation confirms this to a degree that for the present purposes the two genera may be treated as a unit. Preliminary studies of the primary wood of the two genera reveal that this anatomical similarity also holds when those structures are compared.

These two genera exhibit tendencies toward ring-porosity, there usually being a gradient in vessel diameter from the early to late wood. However, a few species of Juglans are definitely ring-porous. The vessels of Pterocarya and of a few species of Juglans are fairly thin-walled and retain their angularity; the fiber-tracheids of these species also possess relatively thin walls. The majority of the species of Juglans, however, tend to have vessels and fibers with slightly thickened walls and vessels which are less angular in outline. Inasmuch as the vessels of both genera show only porous perforations, they are more advanced than those of Engelhardtia and Alfaroa.

The ray type of the two genera is relatively constant, so much so that they can be easily distinguished from those of the other genera. In some species of *Juglans* the rays approximate homogeneity, almost reaching the extreme in specialization for this character.

Manning states that the inflorescences of these two genera are closely related as to type and that those of both genera are advanced. However, he asserts that in both male and female catkins Juglans shows a more specialized condition; also he indicates that the stigmas of these genera are of the same

type. This is in general agreement with the anatomical conditions indicated for the two genera.

Carya shows an abundance of specialized characters-a distinct ring-porosity and rounded, thickwalled vessels with only porous perforations distinguish the genus from the previous genera. The rays are of the same general type as those of Pterocarya and Juglans, though they tend to be wider.

According to Manning, Carya, on the whole, possesses the most specialized condition of the inflorescence in the family. The stigmas are advanced as well, and are distinct from the other types which occur in the family. Here again we find that these facts parallel the anatomical specialization of the genus.

Platycarya, as was previously stated, possesses inflorescences of the primitive type. It is unique in the family in that the bracts of the female portion of the inflorescence are conspicuous and woody. Nevertheless, the wood is ring-porous, the vessels, particularly the large ones, having rounded outlines, slightly thickened walls, and only porous perforations. The small vessels and vascular tracheids with which they are associated possess spiral thickenings. According to Frost (1931), such spiral thickenings give evidence of specialization. The rays are apart from the rays of the other genera in that they are the widest and possess the greatest volume.

Platycarya has a stigma similar to that of Pterocarya and Juglans. But on the basis of xylem anatomy it cannot possibly be allied with these genera, nor can it be considered primitive. Disregarding the situation presented by Platycarya, the results of this investigation closely parallel those of Manning's inflorescence and floristic studies. To explain the anomaly presented by Platycarya, one is forced into the realm of theory. Either the evolution of the inflorescence lagged behind that of the xylem anatomy, or there was an early genetic as well as geographic segregation of the genus, or both. This does not solve the problem but does suggest directions in which further investigation may prove fruitful.

Bailey and Tupper (1918) found that as specialization proceeds in the secondary xylem of the dicotyledons, the fusiform cambial initials become shorter and shorter. Because vessels undergo little if any elongation in ontogeny, their lengths should reflect the approximate lengths of the cambial ini-

tials from which they were derived.

From table 1 it is seen that Alfaroa, with the most primitive vessels, has the longest vessel members. Engelhardtia, the other genus with scalariform vessel perforations, comes next in descending order of vessel member length. Pterocarya is less specialized than Juglans, and it also has longer vessels. Carya, with extreme ring-porosity, thick-walled, rounded vessels with porous perforations, shows a decided shortening in vessel length. Shortest of all are the vessels of Platycarya, and this serves to emphasize the anatomical evidence for specialization in the genus.

The additional figures of the table concerning the vessel members are in line with the evidence for specialization derived from the lengths of these members. Bailey and Tupper (1918), and also Frost (1930a, 1930b), state that accompanying the decrease in length of the vessel members, the diameter increases and the angle of the end wall approaches 90°. Engelhardtia and Pterocarya show little difference in the values for the vessel diameters and for the angles of the end walls of the vessel members. One who works with sections of xylem recognizes that real difficulties exist in obtaining adequate and accurate measurements of vessel diameters and endwall angles from sectioned material. In consequence he utilizes the figures obtained to indicate trends and makes no pretense of having results which can be statistically analyzed. Differences of the order of those existing between Engelhardtia and Pterocarya are insignificant. Especially is this true when dimensions vary with the place of origin of the wood in the stem. The most that can be said is that on the basis of length of vessel segment, Engelhardtia shows less specialization than Pterocarya. On the other hand, though Pterocarya and Juglans are much alike structurally and in the organization of their inflorescences (Manning, 1938a), there are significant differences in the figures provided in table 1. Pterocarya seems distinctly less specialized.

The averages for the lengths of the fibers do not afford data which seem significant in the present connection. As Bailey and Tupper (1918) have indicated, the lengths of the fibrous elements are dependent on (1) the lengths of the cambial initials from which they are derived, and (2) the amount of elongation which they undergo. With the possibility of various internal conditions influencing the lengths of these elements, a greater amount of variation

might be expected.

Thus it is evident that, to a significant degree, the results of Manning's study of the inflorescences of

TABLE 1.

	Vessel member length in $\mu$	$\begin{array}{c} \text{Vessel} \\ \text{diameter} \\ \text{in } \mu \end{array}$	Angle end wall of vessel member	Fiber length in $\mu$
Alfaroa	901	100	45°	1,343
Engelhardtia		146	48°	1,481
Pterocarya		140	470	1,339
Juglans		191	58°	1,503
Carya		246	69°	1,516
Platycarya		193	65°	1,479

the Juglandaceae on the one hand and those of the present investigation of the wood anatomy of this family on the other are in accord with one another. This fact offers support to the opinion that continued attempts to approach a natural classification of the Angiosperms must depend upon the cooperative enterprise of individuals from the various fields of botanical endeavor.

It should be added that, within those genera having several species-viz., Engelhardtia, Pterocarya, Juglans, and Carya—attempts to find lines of xylem specialization which would accord with the existing taxonomic arrangement of the species within each genus, or with the suggested lines of specialization in the inflorescence of each genus as suggested by Manning (1938a), have failed. This may in part be due to lack of adequate anatomical material for a study of the range of xylem types. It is, however, more probable that the anatomist has not yet acquired adequate criteria for such intrageneric studies. Those criteria employed here have proved significant for cooperative investigations with the taxonomist on problems involving major phyletic lines of families or even subfamilies. Much more information is needed before anatomy can be employed for work within the genus. Moreover, there is at present little evidence to suggest that anatomical specialization must follow hand-in-hand with the specializations of the flower or of the inflorescence. It may well be that such has occurred but there seems no a priori reason to suggest that it must do so.

### SUMMARY

Manning (1938a) has utilized evidence obtained from a study of the inflorescences found in the Juglandaceae for an interpretation of generic relationships within the family. The present investigation was undertaken in an effort to determine to what degree a study of the xylem anatomy might confirm his findings. There were available for this study wood specimens from a greater majority of the species of the family. The criteria employed were those now generally recognized as significant in phylogenetic studies based on secondary xylem. The findings are as follows:

Alfaroa seems to be the most primitive genus of the family. Engelhardtia is not dissimilar but is somewhat more advanced. Pterocarya and Juglans are closely allied with many anatomical features in common, though Juglans has reached a somewhat higher degree of specialization. Carya has attained a level of structural organization not found in any other genus. The isolated genus Platycarya seems to have achieved a high degree of organization along an independent pattern of specialization.

The results of this investigation are in striking accord with those of Manning. *Platycarya* alone demands a different interpretation. Manning finds this genus generalized in inflorescence for the family and suggests it as primitive. Anatomical evidence cannot support this belief.

Intensive study of intrageneric variations in anatomy gives few facts to support the idea that the established criteria employed in phylogenetic investigations based on anatomy are adequately refined for intrageneric interpretations.

## GROWTH FACTOR REQUIREMENTS OF FOUR SPECIES OF ISOLATED ROOTS 1

James Bonner and Philip S. Devirian

Although the culture of isolated root tips was reported in 1922 by Robbins and by Kotte, it was not until more than ten years later that White (1934) succeeded in maintaining excised tomato roots in vitro with undiminished growth rate over long periods of time. White found that for the successful culture of tomato roots the addition of a small amount of yeast extract to the nutrient medium was essential. Much of the further work on the cultivation of isolated roots has centered around the identification of the chemical substances responsible for this promotive effect of yeast extract on root growth. Bonner (1937) showed that vitamin B<sub>1</sub>, a component of yeast extract, is essential for the growth of the isolated pea root. A similar relation of vitamin B<sub>1</sub> to the growth of the isolated tomato root has been demonstrated by Robbins and Bartley (1937) and later by White (1937). It has been recognized, however, that vitamin B<sub>1</sub> is not the sole accessory root growth substance supplied by yeast extract. For the pea root nicotinic acid is a second essential factor (Addicott and Bonner, 1938). For the tomato root, on the other hand, vitamin B6 has been shown to be indispensable (Robbins and Schmidt, 1939a, 1939b). In the past, work concerning the root growth factors has centered on the roots of pea and tomato. In the present paper a comparison will be made between the growth factor requirements of the roots of four species of plants.

MATERIALS AND METHODS.—In all the cultures reported here the nutrient solution reported earlier (Bonner and Addicott, 1937) as satisfactory for the growth of isolated pea roots was used. This nutrient solution contains per liter: 242 mg. of Ca(NO<sub>3</sub>)<sub>2</sub>·4H<sub>2</sub>O, 42 mg. of MgSO<sub>4</sub>·7H<sub>2</sub>O, 85 mg. of KNO<sub>3</sub>, 61 mg. of KCl, 20 mg. of KH<sub>2</sub>PO<sub>4</sub>, and 1.5 mg. of ferric tartrate. Sucrose was added to the medium in a final concentration of 4 per cent for roots of pea, radish and flax, and of 2 per cent for tomato roots.

<sup>1</sup> Received for publication June 30, 1939.

Report of work carried out with the cooperation of the Works Progress Administration, Official Project number 665-07-3-83, Work Project number 9809.

Accessory growth factors were made up in concentrated stock solutions so that they could be added, as desired, at the rate of 1.0 cc. of stock solution per liter of nutrient. The final medium was autoclaved at 15 pounds pressure for 25 minutes.

All cultures were carried out in 10 cm. Petri dishes, each dish containing 20 cc. of nutrient solution and 1 to several roots, the number of roots depending inversely on the luxuriance of growth.

Culturing and transferring of the roots were carried out in a culture room which could be steam sterilized. Forceps and knives were sterilized by immersion in alcohol and subsequent flaming. Contaminations by fungi or bacteria were very rare. All cultures were maintained in the dark in an air-conditioned room held at 25 ± 0.5°C.

Roots were in all cases obtained from seedling plants. Seeds were sterilized in 0.1 per cent HgCl<sub>2</sub> and allowed to germinate under asceptic conditions. When the seedling roots were 10-20 mm. long, tips 4-5 mm. long were excised and used for further work.

EXPERIMENTAL RESULTS .- Pea roots .- It is known (Addicott and Bonner, 1938) that isolated pea roots can be maintained in culture over periods of several months (and presumably indefinitely) provided that both vitamin B<sub>1</sub> and nicotinic acid are supplied as growth factors in addition to the nutrient medium described above. In the presence of adequate supplies of vitamin B<sub>1</sub> and of nicotinic acid still other factors, however, must limit the growth of the pea root. The relation of other known or possible plant growth substances to the growth of isolated pea roots in the presence of an excess of vitamin B<sub>1</sub> and nicotinic acid was therefore investigated. In each experiment 500 freshly excised tips (variety "Perfection") were grown for one week in growth factor free medium. At the end of this week 400 roots, as nearly uniform as possible, were subcultured by the removal of 10 mm. tips and divided among the several parts of the experiment. The roots were then subcultured at regular weekly intervals. Table 1 gives the results from one experiment in which ade-

nine (a factor for the growth of leaves, D. Bonner and Haagen-Smit, 1939) and vitamin B62 were used as additions to vitamin B1 and nicotinic acid. Concentrations of adenine above 0.5 mg. per liter were found to be inhibitory and 0.1 mg. per liter was therefore used. Vitamin B6 was used at the concentration of 0.1 mg. per liter, a concentration satisfactory for the maintenance of isolated tomato roots. (See below.) It is evident from table 1, however, that neither of these known plant growth factors exerted any significant effect on the growth of pea roots over the 12-week experimental period. In table 2 are presented results from a similar experiment with vitamins E, K, and B2.2 Vitamin E was given as pure tocopherol, vitamin K as a purified concentrate, and vitamin B2 as crystalline riboflavin. As may be seen in table 2, none of these substances exerted a significant effect on the growth of pea roots over the 14-week experimental period. These substances were also used in concentrations 10 or 100 times lower than those given in table 2 without significantly different results. Pantothenic acid, β-alanine,2 ascorbic acid, and theelin were likewise without effect over wide ranges of concentration. Addicott (1939) has reported 20 amino acids as being without significant growth factor effect on the growth of pea roots in the presence of vitamin B1 and nicotinic acid.

It may then be concluded that the growth of pea roots in the presence of vitamin  $B_1$  and nicotinic acid is not limited by any of the above substances and growth factors. It is of particular interest that adenine, known to be a growth factor for leaves, and vitamin  $B_6$ , known to be a growth factor for tomato roots, are neither essential nor promotive to the growth of isolated pea roots under the present experimental conditions.

Radish roots.—Two hundred and fifty tips from the roots of asceptic radish seedlings (variety "Scarlet Globe") were excised and cultured in media of the compositions shown in table 3. Two transfers were made at weekly intervals and two further transfers at two weekly intervals. At the end of this time a parallel series of cultures in 2 per cent sucrose me-

<sup>2</sup> We are indebted to Prof. Samuel Lepkovsky, Berkeley, for the crystalline vitamin  $B_6$ ; to Dr. R. T. Major, Merck and Co., Inc., for the supply of vitamins E, K, and  $B_2$ ; and to Prof. R. J. Williams, Corvallis, for the pantothenic acid and the β-alanine.

Table 3. The growth factor requirements of excised radish roots. Mineral nutrient of basic pea root medium and 4 per cent sucrose used in all cases.

Added growth factors	Observations
None	Ceased growth after 4th transfer
Vitamin B <sub>1</sub> 0.1 mg./l	Ceased growth after 4th transfer
Nicotinic acid 0.5 mg./l.	Growth slight after 4th transfer
$B_1$ + nicotinic acid	Growth constant at approxi- mately 30 mm. per 2 weeks for 14 transfers
Yeast extract 0.01%	Growth identical with that in $B_1 + nicotinic$ acid medium

<sup>a</sup> The yeast extract was made by boiling 1 gram of dried brewer's yeast in 100 cc. of water for 30 minutes, filtering, and making up to 100 cc. One cc. of this extract, representing the water soluble portion of 10 mgs. of dried yeast, diluted to 100 cc. is referred to as 0.01 per cent yeast extract.

dium had ceased their growth. Of those in 4 per cent sucrose medium, the control (which received no accessory growth substances), and the vitamin B<sub>1</sub> cultures also showed no new growth. The cultures which received nicotinic acid grew only to a limited extent. However, if yeast extract or vitamin B<sub>1</sub> and nicotinic acid together were present in the medium, growth of the isolated radish roots was vigorous, as is shown in figure 1. No significant differences in luxuriance of root growth between yeast extract and vitamin B<sub>1</sub>-nicotinic acid cultures could be detected, and it would therefore appear that this combination of pure crystalline growth factors is capable of completely replacing yeast extract for the radish root. The roots of the vitamin B<sub>1</sub>-nicotinic acid series were increased in number by propagation from secondary root tips and were kept in culture through 14 transfers over a period of 6 months. During this time the average growth rate was maintained at approximately 30 mm. per root (as judged by the longest root produced by each fragment) per two weeks. Since this growth rate is slow compared to that of pea or tomato roots, numerous attempts to increase it were made. Additions of vitamins E, K, and B2, pantothenic acid, adenine, the known minor elements, or of the amino acids asparagin, glutamic acid, glycine, isoleucine, leucine, tryptophane, and valine were all without influence on the growth rate. Vitamin B<sub>6</sub> also was completely without effect. White (1938) has reported the culture of excised radish roots in yeast extract medium through several passages at an average growth rate of 13.5 mm. per day. White does not give the variety with which he worked, but it seems probable that it may have differed from that used in the present work. In any event, it is possible to culture radish roots of the present variety through 14 passages (and hence presumably indefinitely) in a medium containing only vitamin B<sub>1</sub> and nicotinic acid as accessory growth factors. It might be noted that no "radishes" were formed in any of these cultures of isolated roots, and none would be expected, since the "radish" is largely a hypocotylar structure in the globe types (Havward, 1938).

Flax roots.—Approximately 500 root tips were removed from asceptic flax seedlings (unnamed variety) and maintained for one week in the standard pea root medium with 4 per cent sucrose. At the end of this week, during which the roots grew an average of approximately 150 mm., they were transferred to media either with or without vitamin B1. The roots were then subcultured weekly into fresh media of the same composition. The growth rate of the roots which received no vitamin B<sub>1</sub> declined steadily. Those roots which received B1, however, grew luxuriantly and maintained a growth rate of more than 2 cm. per day through 14 weekly transfers. The addition of either nicotinic acid or vitamin B6 to the medium in which flax roots were cultured resulted in no further increase of growth rate (table 4). Vita-

Table 4. Growth of isolated flax roots in media of different composition. Mineral nutrient of basic pea root medium and 4 per cent sucrose was used in all cases.

Added growth factors	Observations
None	Growth declined to 67 mm. per week after 5 weeks
Vitamin B <sub>1</sub>	Growth maintained at an average of 158 mm. per week
Nicotinic acid	Growth declined to 60 mm. per week after 5 weeks
Vitamin B <sub>6</sub>	Growth declined to 61 mm. per week after 7 weeks
$B_1 + nicotinic acid$	Growth maintained at an average of 165 mm. per week
$B_1 + B_6 \dots$	Growth maintained at an average of 153 mm. per week
Nicotinic acid $+ B_6 \dots$	Growth declined to 43 mm. per week after 7 weeks

min  $B_1$  is apparently the only necessary growth factor required for the luxuriant growth in vitro of isolated flax roots.

Tomato roots.—Tips from two hundred asceptic tomato seedlings (variety "Beefsteak") were cultured in medium containing 2 per cent sucrose and

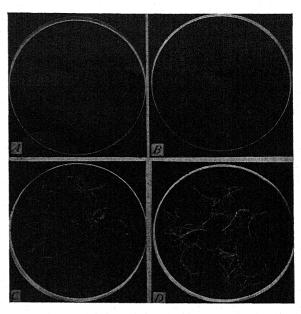

Fig. 1. Growth of isolated radish roots in different media. Photographed 2 weeks after the 4th subculturing. Approximately the same number of initial root tips was used in each case. A, basic media + vitamin B<sub>1</sub>, 0.1 mg./l.; B, basic medium + nicotinic acid, 0.5 mg./l.; C, basic medium + 0.01 per cent yeast extract; D, basic medium + vitamin B<sub>1</sub>, 0.1 mg./l. + nicotinic acid, 0.5 mg./l.

0.01 per cent yeast extract in addition to the standard mineral nutrient. At the end of one week, the 10 most vigorous roots were selected and a clone established from each. One of these 10 clones exhibited a considerably greater luxuriance of growth than did the other 9 and was hence selected for all the work reported below. Roots from this clone were maintained through 12 weekly passages on a medium containing only vitamin B<sub>1</sub> and nicotinic acid as acces-

Table 5. Growth of excised tomato roots in media of different composition. Mineral nutrient of basic pea root medium and 2 per cent sucrose used in all cases.

Added growth factors	Observations
None	Growth ceased after 2nd trans- fer
Vitamin B <sub>1</sub>	Growth ceased after 2nd transfer
Nicotinic acid	Growth ceased after 2nd trans- fer
Vitamin B <sub>6</sub>	Growth ceased after 3rd trans- fer
B <sub>1</sub> + nicotinic acid	Growth slow (approximately 10 mm. per week), discarded after 3 weeks
Nicotinic acid $+ B_6$	Growth ceased after 3rd trans- fer
$B_1 + B_6 \dots$	Growth maintained at 40 mm. per week for 18 weeks
$B_1 + nicotinic acid + B_6$	Growth maintained at 60 mm. per week for 20 weeks

sory growth factors. Growth was maintained at approximately 10 mm. per week. At the end of this time, the roots were subcultured into the media shown in table 5. Vitamin B<sub>6</sub> in combination with vitamin B1 exerted a striking promotive effect on the growth of these isolated tomato roots, a finding in agreement with and corroborating that of Robbins and Schmidt (1939a). Roots cultured in medium containing these two growth factors grew at an average rate of 40 mm. per week. Table 5 shows in addition that this growth rate may be increased to approximately 60 mm. per week through the addition of nicotinic acid to the medium. Neither vitamin B1, nicotinic acid, nor vitamin B6 alone was able to support growth at any appreciable rate. It would seem justifiable to conclude, therefore, that this clone of tomato roots is heterotrophic for vitamin B1 and vitamin B<sub>6</sub>, and to some extent also for nicotinic

It has been reported (Robbins and Bartley, 1937) that the vitamin B<sub>1</sub> thiazole (4 methyl, 5-\beta-hydroxyethyl thiazole) is capable of replacing vitamin B1 in the nutrition of isolated tomato roots. During the course of the present investigation a few observations on the growth of tomato roots in thiazole solutions were made. These are summarized in table 6. Roots of the present clone grown in medium containing only vitamin thiazole as an accessory growth factor completely ceased their growth after two transfers. Roots grown in medium containing vitamin B6 in addition to the vitamin thiazole decreased steadily from an initial growth rate of 45 mm. per week to 0 mm. per week after nine weeks. If nicotinic acid was also present in the medium, growth declined from an initial rate of approximately 65 mm.

Table 6. Effect on the growth of isolated tomato roots, of replacing vitamin B<sub>1</sub> by vitamin thiazole. Mineral nutrient of basic pea root medium and 2 per cent sucrose used in all cases.

Added growth factors Observations		
Vitamin thiazole	Growth ceased after 2 weekly transfers	
Vitamin thiazole + vita-		
min B <sub>6</sub>	Growth declined to 0 during 9 weekly transfers	
Vitamin thiazole + vitamin B <sub>6</sub> + nicotinic		
acid	Growth declined to 8 mm. per week during 9 weekly trans- fers	
Vitamin B <sub>1</sub> + nicotinic		
acid $+$ vitamin $B_6$	Growth maintained at 60 mm.	

per week to 8 mm. per week after nine weeks. At the end of this time the roots were short and slender in comparison to the parallel series of roots which received vitamin  $B_1$  rather than vitamin thiazole, and were discarded. Tomato roots of the present clone can therefore not thrive when supplied with vitamin thiazole in place of vitamin  $B_1$ , and it may be con-

per week

cluded that they synthesize little if any vitamin pyrimidine. This conclusion is supported by direct assays for vitamin  $B_1$  made with the *Phycomyces* test (Schopfer and Jung, 1937; Bonner and Erickson, 1938) on tomato roots cultured for five weeks with nicotinic acid and vitamin  $B_6$  plus either vitamin  $B_1$  or vitamin thiazole. The roots supplied with vitamin  $B_1$  contained more than ten times as much of this substance as roots cultured with vitamin thiazole.

Discussion.—The isolated roots of the four species of plants reported here differ as to their accessory growth factor requirements. Thus, isolated roots of flax require vitamin  $B_1$  alone, roots of radish and pea require vitamin  $B_1$  and nicotinic acid, and roots of tomato require vitamin  $B_1$ , nicotinic acid, and vitamin  $B_6$  for maximum rate of growth. It might be suspected that vitamin  $B_6$  is essential to the growth of pea, flax, and radish roots and that nicotinic acid also is required by roots of flax but that these requirements are met by in vivo synthesis of the substances in the several cases. The nature of such possible in vivo synthesis of accessory growth factors by isolated roots, however, will be the subject of future communications.

### SUMMARY

Isolated pea roots can be cultivated indefinitely in nutrient medium containing vitamin  $B_1$  and nicotinic acid in addition to mineral salts and 4 per cent sucrose. The growth rate in this medium is 70–85 mm. per week. Vitamin  $B_6$ , adenine, ascorbic acid, theelin,  $\beta$ -alanine, pantothenic acid, vitamins E, K, and  $B_2$ , and numerous amino acids are without effect in increasing the growth rate of isolated pea roots in the presence of vitamin  $B_1$  and nicotinic acid.

Isolated radish roots were cultivated through 14 passages over a period of six months at an average growth rate of 30 mm. per two weeks in medium containing vitamin  $B_1$  and nicotinic acid in addition to the basic nutrient. Both vitamin  $B_1$  and nicotinic acid were essential for the maintenance of growth. Vitamins  $B_6$ , E, K, and  $B_2$ , adenine, pantothenic acid, and numerous amino acids were without influence on the growth rate.

Isolated flax roots were cultivated through 14 weekly transfers at an average growth rate of approximately 150 mm. per week. Vitamin  $B_1$  is the only accessory growth factor required by the present strain of flax roots. Additions of vitamin  $B_6$  or nicotinic acid were without significant effect on the growth rate.

In confirmation of earlier work by others (Robbins and Schmidt, 1939a), it is shown that isolated tomato roots can be cultivated indefinitely at an average growth rate of 40 mm. per week in medium containing only vitamins  $B_1$  and  $B_6$ . The growth rate, however, could be increased to 60 mm. per week by the addition of nicotinic acid to the medium.

# THE PATH OF FLUORESCEIN MOVEMENT IN THE KIDNEY BEAN, PHASEOLUS VULGARIS <sup>1</sup>

## Edward M. Palmquist

The technique developed by Schumacher (1933) for following visually the path of a non-toxic solute as it moved in plants extended the possible scope of experiments dealing with translocation. Using this technique, in an attempt to determine whether or not two different solutes could move simultaneously in opposite directions in the same phloem tissue, the writer (1938) corroborated Schumacher's finding that fluorescein moved in the phloem if proper precautions were taken. The evidence for this was merely the detection of the greenish yellow fluorescence, characteristic of fluorescein, in the phloem of the petioles of bean leaves to which fluorescein had been applied. This fluorescence was absent in the petioles of untreated leaves.

It was also found that under certain conditions fluorescein can be made to move more rapidly in the xylem than in the phloem. When the cut end of a stem was immersed in fluorescein solution, for example, the solute rose rapidly in the xylem. Likewise, when a scraped leaf of a water deficient plant was immersed in fluorescein solution the solute moved rapidly out of the leaf through the xylem. It also moved rapidly in the xylem from an immersed tip of a potato sprout toward the shrivelling tuber. In each of these instances in which movement occurred in the xylem, there was undoubtedly a corresponding mass movement of water. In the cut stems, fluorescein moved with the transpiration stream, and in the other two illustrations there was a mass movement of water in the xylem from the immersed portion toward parts of the plant which were deficient in water. It would indeed be hard to visualize a mecha-

<sup>1</sup> Received for publication July 6, 1939.

nism in plants which would prevent the movement of fluorescein, or any other solute, with the transpiration stream, once it had entered the xylem. Fluorescein cannot be carried along in this manner in well watered or turgid plants which exhibit little or no mass movement of water.

Rhodes (1937) has added a new line of evidence from which he concludes that fluorescein moves in the xylem and that the apparent movement in the phloem is merely the result of lateral diffusion into that tissue following the movement in the adjacent xylem. He found, as did Schumacher, that after the application of fluorescein to a leaf, sections of the stem below the treated leaf showed the characteristic vellow fluorescence in the phloem and not in the xylem. He pointed out, however, that fluorescein might be present in the xylem in a non-fluorescent state, since it does not fluoresce strongly in acid solution, and the sap of most plants is acid. He therefore exposed his sections to ammonia vapor before examination and found that in sections of the stem immediately below a fluorescein treated leaf, both xylem and phloem showed the characteristic yellow fluorescence, and further, that as sections were taken progressively farther away from the treated leaf, fluorescence was present in the xylem below the point where it faded out in the phloem. This evidence at first sight seems to indicate strongly that either fluorescein moves more rapidly in the xylem than it does in the phloem, or it moves only in the xylem and subsequently diffuses laterally into the adjacent phloem.

Schumacher (1937), however, using fluoresceintreated plants of *Pelargonium*, found that ammonia

vapor treatment did not bring about fluorescence in the xylem. He points out that Rhodes did not follow his gelatin block method of applying fluorescein but instead immersed leaves in aqueous solutions. He assumes that with this method Rhodes probably introduced fluorescein into the xylem where it could move with the transpiration stream.

The writer (1938) has pointed out that many plants possess inherent fluorescent compounds, some of which, under the stimulation of blue and violet light, emit a yellowish fluorescence practically identical to that of fluorescein. Many untreated woody plants were examined under the fluorescence microscope, and without exception the xylem showed some yellowish florescence, although the intensity of this fluorescence varied greatly. The effect of ammonia vapor on the fluorescence of these woods was ascertained. Cross sections of twigs were exposed to ammonia vapor for three minutes before examining. In all the twigs so treated the xylem fluoresced with a brilliant yellow light. These plants had not been treated with fluorescein. With one exception (Berberis) the same sections when exposed to hydrochloric acid fumes lost this fluorescence, but regained it after a second exposure to ammonia vapor. A list of some of the genera examined and a description of the natural fluorescence in the xylem are given in table 1.

It is apparent from these data that the selection of material is a most critical task in the preparation of experiments with fluorescein. The use of plants which show natural fluorescence, similar to that of fluorescein, whether treated with ammonia vapor or not can lead only to confusion. Of all the plants examined, the common red kidney bean (Phaseolus vulgaris L.) has proved most satisfactory. Sections taken from the young parts of this plant show no fluorescence in the xylem, either with or without the ammonia treatment. In the old parts of this plant. however, and also in those of *Pelargonium*, the plant used originally by Schumacher, the xylem shows a yellow fluorescence when treated with ammonia vapor. In addition to the careful selection of material, it is essential that mass movement of water in the xylem be prevented or at least recognized. It should be obvious that a cut stem, exposed to conditions which allow transpiration, with its base immersed in fluorescein solution will rapidly take up the solution in its xylem and that an intact but water deficient plant will do likewise if a leaf or stem tip is immersed in fluorescein solution.

THE PATH OF FLUORESCEIN MOVEMENT IN BEAN PLANTS.—Last July, twenty young potted bean plants were moved from the greenhouse to a dark room and watered thoroughly. The terminal leaflet from one compound leaf on each plant was gently scraped and immersed in a one-tenth per cent fluorescein solution. A short section of the rachis was scalded on ten leaves. Three hours later one lateral leaflet was removed from each of the treated leaves and examined macroscopically for fluorescence. The leaflets from the leaves with scalded rachises showed no fluorescence, while those from leaves the rachises of which had not been scalded showed brilliant fluorescence along the veins. Twenty-one hours later the second lateral leaflet was removed from each of the twenty leaves. The results here were identical with those observed after three hours, except that at this time two of the ten leaflets from the scalded leaves showed fluorescence along the veins.

Cross sections of the stems below the treated leaves were examined under the fluorescence microscope. Those taken from plants with scalded rachises showed no fluorescein in either xylem or phloem, while those from plants with unscalded rachises were brilliantly fluorescent in the phloem. Similar sections were exposed to ammonia vapor for three minutes. This treatment did not bring about any change in the fluorescence of the conducting tissues. No fluorescein could be detected in the xylem of any of the plants.

From these facts it was concluded that under conditions which prevent a mass movement of water in the xylem, the tissue that conducts fluorescein in bean plants is the phloem.

### SUMMARY

Schumacher reported that fluorescein moves in the phloem. Later, Rhodes concluded that it moves in the xylem, but ordinarily is not detectable there without raising the pH, and that the apparent movement in the phloem results from the lateral diffusion into that tissue from the adjacent xylem. Cross sections of untreated twigs, representing twenty-five genera, were examined with a fluorescence microscope. Most of these showed a trace of yellow fluo-

rescence in the xylem. These sections were then exposed to ammonia vapor. The xylem of all of them fluoresced with a brilliant yellow light similar to that of fluorescein. These twigs had not been treated with fluorescein. The xylem of young bean plants does not fluoresce, either with or without the ammonia treatment. Fluorescein was applied to a series of thoroughly watered bean plants. Twenty-four hours later, cross sections of the stems showed fluorescence in the phloem, but not in the xylem. Exposure to ammonia vapor failed to produce fluorescence in the xylem. It is concluded that fluorescein moves in the phloem of bean plants.

## A SECOND GROWTH FACTOR FOR EXCISED PEA ROOTS: NICOTINIC ACID <sup>1</sup>

Frederick T. Addicott and Philip S. Devirian

WHITE (1934) has shown that it is possible to cultivate excised tomato roots indefinitely under sterile conditions. The medium which he used contained yeast extract in addition to salts and sugar. Subsequent workers have directed their attention to the determination and study of the substances in yeast extract which are necessary for the growth of roots. Bonner (1937), working with pea roots, and Robbins and Bartley (1937), working with tomato roots, simultaneously and independently showed that vitamin B<sub>1</sub> was an essential component of the yeast extract in which roots of both these plants had previously been grown. However, it soon became evident that vitamin B<sub>1</sub> could not completely replace yeast extract; when supplied as the only accessory substance, it would not support the indefinite growth of pea roots. This paper reports the results of a search for the other growth factor(s) of excised pea roots. A preliminary note on this work was recently published (Addicott and Bonner, 1938).

Метнорs.—The methods used in this work have already been discussed in detail (Bonner and Addi-

<sup>1</sup> Received for publication June 20, 1939.

Report of work carried out with the assistance of the Works Progress Administration, Official Project Number 665-07-3-83, Work Project Number L-9809.

cott, 1937); so they need only be mentioned briefly here. Seeds of garden peas (Pisum sativum) of the variety Perfection were germinated under sterile conditions. At the end of two days 5 mm. of the root tip was removed and placed in a 10 cm. Petri dish containing 20 ml. of liquid culture medium. At the end of each succeeding week 10 mm. of the root tip was removed and transferred to fresh medium. The process of weekly subculture was repeated for the duration of each experiment. All the cultures were made under aseptic conditions. The following salts were used in the basic medium:  $(Ca(NO_3)_2 \cdot 4H_20$ , 236 mg.; MgSO<sub>4</sub>·7H<sub>2</sub>O, 36 mg.; KNO<sub>3</sub>, 81 mg.; KCl, 65 mg.; KH<sub>2</sub>PO<sub>4</sub>, 20 mg.; Fe-tartrate, 1.5 mg.; all in 1 liter of double distilled water. The medium also included 4 per cent sucrose as a source of carbohydrate. The substances under consideration were tested for their ability to increase root growth in length during the second weekly transfer, always in the presence of vitamin B<sub>1</sub> (0.1 mg. per liter). Twenty or more roots were used to test the effects of each concentration. If a substance showed signs of activity under these conditions tests were continued through a series of subcultures.

OBSERVATIONS.—It had been suggested in the literature that the second growth factor in the case of tomato roots might be among the microelements (Robbins, White, McClary, and Bartley, 1936; Robbins and Schmidt, 1938) or among the amino acids of yeast extract (White, 1937). The preliminary experiments of Bonner and Addicott (1937) also indicated that the amino acids might be a source of growth factors for pea roots. Both these types of substances were investigated.

The ash of pea seeds was first utilized as a source of microelements, since it is well known that the seed is capable of supplying all the nutritional requirements of a young plant for some time. However, this was found to be completely inactive (table 1).

Higher concentrations of the ash inhibited growth, and as dilution progressed, growth approached that of the controls. White's (1938) supplementary salt solution was also tested, alone and in combination with an arbitrary mixture of salts. The latter included additional elements known to occur in the Leguminosae and other plants (table 2, 3). With

these, likewise, no dilution or mixture was found in which the roots grew to a greater extent than they would with vitamin  $B_1$  alone in standard salts and sugar. In the hope that these negative results were due to the presence of one or more salts in concentrations inhibitive to growth, some experiments were run using single salts. These were also negative, additional zinc, manganese, copper, and tungsten being without significant effect (table 4). This list would have been extended had it not appeared in experiments which will be discussed shortly that the limiting factor under the above conditions was nicotinic acid and not to be found among the inorganic substances at all.

The search for the additional growth factor was next carried to the amino acids. Twenty of the highest purity available were selected for use in a series of experiments. These were: alanine, arginine, asparagine, aspartic acid, cystein, cystine, glutamic acid, glycine, isoleucine, leucine, lysine, methionine, ornithine, phenyl-alanine, proline, serine, tryptophane, tyrosine, and valine. Each amino acid was tested singly and in combination with other acids for its effect on growth during the second weekly transfer. Ten were found to increase root growth significantly over that of the controls receiving only vitamin B<sub>1</sub>. In order to obtain the optimum mixture of amino acids, each of these ten was tested in three concentrations in the presence of the other nine. The results of this experiment are shown in table 5,

Table 5. Effect of ten selected amino acids on the growth of pea roots.<sup>a</sup>

	Concentration			Value of	
Acid	10 X	1 X	0.1 X	1 X in mg. per liter

<sup>\*</sup> Growth is expressed as the percentage of the length of the control roots which were given all the amino acids (at the concentration of 1 X) except that acid being studied.

showing the optimum concentration of each acid in the presence of the others. It also shows that it was possible to dispense with three of the acids. Remaining were: asparagine, glutamic acid, glycine, isoleucine, leucine, tryptophane, tyrosine, and valine. This combination of amino acids in the concentrations indicated should be optimum for the growth of pea roots.

In order to determine if this mixture could supply the other growth factor(s), it with vitamin  $B_1$  was added to the medium of a series of roots for a period of ten weekly subcultures. Control roots received only vitamin B<sub>1</sub> as an accessory growth substance. In this experiment 250 roots were used. While these cultures were in progress results became available from experiments in which the effects of various other substances, known to be growth factors for either bacteria or fungi, had been tested. From these it appeared that nicotinic acid had a considerable effect on root growth during the second transfer. In order to determine if this would persist in later subcultures, nicotinic acid (0.5 mg. per liter) was added to the medium of part of the roots which had been receiving vitamin B<sub>1</sub> and amino acids in the above experiment. The series was then continued through 10 weekly subcultures in three parts: roots receiving (a) vitamin B<sub>1</sub> alone, (b) vitamin B<sub>1</sub> plus amino acids, (c) vitamin B<sub>1</sub> plus amino acids plus nicotinic acid. The results of this experiment are shown in table 6; and shadow photographs of the

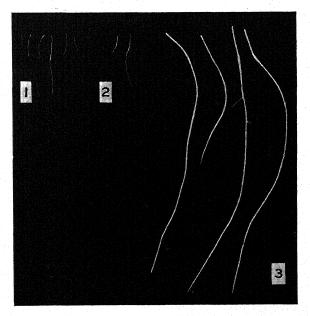

Fig. 1-3. Shadow photographs of roots at the end of the 10th transfer.—Fig. 1. Supplied vitamin  $B_1$  only.—Fig. 2. Supplied vitamin  $B_1$  and amino acids.—Fig. 3. Supplied vitamin  $B_1$ , amino acids, and nicotinic acid. (Five mm. have been removed from the tip of each root.)  $\times 0.8$ .

roots at the end of the tenth transfer appear in figures 1 to 3. From these it is clear that neither vitamin  $B_1$  nor the amino acid mixture with vitamin  $B_1$  is capable of supporting growth indefinitely. However, roots which had received nicotinic acid in addition to the amino acids and vitamin  $B_1$  were growing at a more rapid rate at the end of ten weeks than they were at the start.

Other experiments, which need not be described in detail here, have shown also that nicotinic acid alone could not support root growth for more than a few weeks. It now remained only to be determined whether or not the amino acids were necessary in the successful combination of vitamin B<sub>1</sub>, amino acids, and nicotinic acid found in the above experiment. Consequently a series was started in which part of the roots were placed in medium containing only vitamin B<sub>1</sub> and nicotinic acid as accessory growth factors; the remainder received both these substances and the amino acids in addition. This experiment, started with nearly 500 roots, has at the time of writing extended over 31 weekly subcultures. As the growth rates of figure 4 show, nicotinic acid with

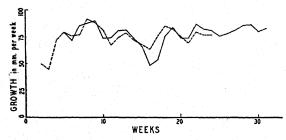

Fig. 4. Weekly growth rate of pea roots over 31 transfers. Solid line: vitamin  $B_1$  and nicotinic acid. Dotted line: amino acids, vitamin  $B_1$ , and nicotinic acid.

vitamin  $B_1$  is completely capable of satisfying the accessory substance requirements of pea roots for indefinite growth. In the presence of these two substances growth (77.1 mm. per week) is even greater than it is in the presence of an optimum concentration of yeast extract (about 60 mm. per week). There was no indication that the amino acid mixture had any effect on the growth rate of the roots when both nicotinic acid and vitamin  $B_1$  were also present in the medium.

Discussion.—It can now be considered as demonstrated that pea roots can grow indefinitely when supplied only vitamin B<sub>1</sub> and nicotinic acid as accessory growth substances. It is of interest to note that the requirements of the roots are so simple. It would not have been surprising if several or many substances of a hormonal nature were required by the isolated roots. The evidence indicates clearly that pea roots when supplied salts, sugar, vitamin B<sub>1</sub>, and nicotinic acid are capable of synthesizing all the proteins, hormones, enzymes, and other substance, both simple and complex, necessary for the formation of living material and for indefinite growth. This growth involves not only increase of

root material but active and continued cell divisions.

It is not surprising that nicotinic acid should be a growth factor for higher plants (its effects on other roots and intact plants are now under investigation in these laboratories), since it is known to be essential to the growth of several microorganisms. Knight (1937) has found it to be necessary for the growth of Staphylococcus aureus. Nicotinic acid is also a growth factor for Staphylococcus albus (Koser, Finkle, Dorfman, Gordon, and Saunders, 1938), for Bacillus proteus (Fildes, 1938), for the dysentery bacillus (Koser, Dorfman, and Saunders, 1938), and for the diphtheria bacillus (Mueller, 1937).

In the bacteria which have been investigated, nicotinic acid amide (the pellagra preventative vitamin) has been found of equal activity with nicotinic acid. In the case of pea roots the preliminary work of Bonner and Buchman (unpublished) with various chemical analogs of nicotinic acid has likewise indicated that the acid amide is as active as the substance itself. This would support the idea that either they are both readily converted by the root to an active form or else that they are both equally active. The first interpretation seems the more likely since nicotinic acid amide is known to be the active part of at least two dehydrogenase systems. The possible action of nicotinic acid through such a system in the root has not yet been investigated.

As shown above, roots cultured in medium containtaining nicotinic acid with vitamin B1 attain in a few weeks a growth rate considerably above the initial rate. Whereas, if yeast extract is given as the source of accessory growth substances, the rate remains at about the initial level. The rise in rate of root growth during the first few weeks in vitamin B<sub>1</sub>-nicotinic acid medium may be due to changes in the auxin content. Van Overbeek (in press) has shown that the root tips at the time of removal from the seed have a high auxin content while as subcultures progress the level falls to a lower point at which it is maintained through production by the root. It has been known that it is possible to inhibit root growth by the application of auxin (Kögl, Haagen-Smit, and Erxleben, 1934). So it is likely that the high initial content is inhibitory to maximum growth and that as the auxin concentration falls, the growth rate increases to a higher level. The reason for the growth rate of the roots in yeast extract remaining close to the initial level is not clear. It may be that the relative concentrations of vitamin B<sub>1</sub> and nicotinic acid are not optimum or that there are substances in the extract which are slightly inhibitory to growth. A third possibility is based on the fact that the Avena seedling is capable of changing tryptophane to indole-acetic acid. It may be that the pea root also forms auxin in this manner, from the tryptophane in yeast extract, thus augmenting its natural content to the point that growth is partially inhibited.

The effects of nicotinic acid on the anatomy of the root are now under investigation and will be reported in a separate paper. It is clear, however, that nicotinic acid, like vitamin  $B_1$ , must be supplied to

the roots if cell divisions are to take place in the meristem.

#### SUMMARY

An essential growth factor for excised pea roots, necessary in addition to vitamin  $B_1$  and present in yeast extract, was not found to be among the amino acids nor the microelements of plant nutrition.

Nicotinic acid can act as this growth factor. Salts, sugar, vitamin B<sub>1</sub>, and nicotinic acid can support the growth of pea roots indefinitely.

### PACIFIC SECTION

Abstracts of the papers presented before the Pacific Section of the Botanical Society of America, Stanford University, California,

June 26 to 30, 1939

How does the little leaf disease affect the MERISTEM OF TREES? H. S. Reed, University of California, Berkeley, Calif.—Dwarfed shoots and leaves are characteristic of apricot and peach trees affected with the little leaf disease. The cytological aberrations of the meristematic region of affected shoots lead to hyperchromatization, vacuolization, and polarization of the cell contents. Tannic compounds are most abundant in early spring and late autumn. They are conspicuous in partially differentiated cells of the sub-apical region. All mitosis is inhibited in these cells. Phloroglucinol is most abundant in the phloem and medullary rays of affected apricot shoots about 5 mm. long in March when tannic compounds have disappeared. In June shoots of healthy apricot trees contain large amounts of phloroglucinol in the cortex, then in smaller amounts in medullary rays, pith and phloem. In general there is parallelism between the amounts of starch and phloroglucinol in the apricot shoots.

STUDIES OF THE DEVELOPMENT OF THE CARROT ROOT. Katherine Esau, University of California, Davis, Calif.—Vascular differentiation begins with the delimitation of a diarch plate through enlargement and vacuolation of the future vessels. Two protophloem sieve tubes are the first vascular elements to mature, and appear opposite each other next the pericycle. Then follows the differentiation of two protoxylem elements on the opposite marginal points of the future xylem plate. The usual centripetal differentiation of further xylem and phloem elements follows. A few centrifugal xylem elements complete the primary development. Oil ducts in the pericycle form two arcs each with the central duct located opposite a protoxylem pole. The hypocotyl resembles the root. In the cotyledons the endarch xylem appears first and the cotyledonary traces appear close below the insertion of the cotyledons. The lateral roots arise near the protophloem poles in the part of the pericycle that lacks oil ducts. In the lateral root development the endodermis forms a temporary covering over the young organ. The fleshy hypogeous storage organ of Daucus carota results from secondary growth in the root and hypocotyl. Cambium arises in the usual manner and forms highly parenchymatous secondary vascular tissues. The cortex is ruptured and shed. A parenchymatous periderm arises by active divisions in all pericyclic cells. Cork cambium and cork appear in the peripheral layers of the periderm outside of the oil ducts. The mature storage organ consists mainly of secondary vascular tissues, the periderm forming a narrow peripheral zone.

THE NATURE OF THE END WALLS OF VESSEL MOTHER CELLS. Katherine Esau and W. B. Hewitt, University of California, Davis, Calif.—The differentiating vessels of herbaceous angiosperms retain the partitions separating the individual elements until the latter reach their final volume. At this time each partition consists of two peripheral cellulose layers the two primary walls—and an isotropic intercellular substance between them. The end walls break

down when the cytoplasm disintegrates.

DEVELOPMENT OF THE FLOWER OF ANTIRRHINUM MAJUS L. Sam E. Keeton, University of California, Davis, Calif. (Read by Katherine Esau.)—The organs of the individual flowers appear in acropetal manner. In the calvx whorl the two abaxial sepals appear simultaneously, followed by the development of the three adaxial ones. The middle sepal of the upper trio is the last to form. The corolla lobes all become evident at the same time and alternate with the sepals. The tubular portion of the corolla results from the upward growth of a ring of tissue beneath the five corolla lobes. The epipetalous stamens alternate with the corolla lobes and appear shortly after the initiation of the corolla. The lower two stamens form first, followed by the two lateral ones, and lastly by the fifth upper stamen, which is normally suppressed at a very early stage. The bicarpellate ovary, imposed upon a fleshy disk, is the last floral organ to appear. The numerous anatropous ovules are borne on a thick axial placenta.

PRELIMINARY REPORT ON THE COMPOSITION OF THE CELL WALLS IN SPHAGNUM. George B. Rigg and Vida Goheen, University of Washington, Seattle, Wash.—The only substances found in the cell walls of Sphagnum are pectic substances indicated by a positive test with ruthenium red, and cellulose, indicated by its swelling and dissolving in cuprammonia following the removal of pectic substances with dilute oxalic acid and ammonium oxalate. Quantitative tests indicated that the content of pectic substances was above 60 per cent. The staining reactions should be supplemented by chemical analysis.

GERMINATION AND SEEDLING DEVELOPMENT OF CERTAIN DESERT PERENNIALS. T. D. Mallery, Desert Laboratory of the Carnegie Institution of Washington, Tucson, Ariz.—Seeds of ninety-four desert perennials representing thirty-four families were planted in soil under greenhouse conditions. The cultures were observed for germinative response and seedling characteristics and development. Fifty-one species germinated. Most species gave a very erratic germinative response. New seedlings appeared from time to time over a period of weeks. The juvenile forms of several species look quite unlike the mature plants. This is strikingly true of Holacantha Emoryi and Canotia Holacantha which change from a leafy to a leafless form. Practically all of the seedlings grew well in the greenhouse where conditions were considerably more mesic than out-of-doors.

THE FOUR STRAND STRUCTURE OF MEIOTIC CHRO-MOSOMES IN ALOE AND LILIUM. G. A. McCallum. Stanford University, Calif. (Introduced by L. L. Burlingame.)—The diakinesis chromosomes of Aloe striata contain two chromatids and each chromatid consists of a pair of twisted chromonemal threads. The metaphase coiling obscures these chromonemata. At anaphase the chromatids are in diads and each contains a coiled chromonema which is visibly double at late anaphase and early telaphase. In Lilium parvum the chromosomes show four chromonemata at diakinesis.

NEW AND INTERESTING RHODOPHYCEAE FROM SOUTHERN CALIFORNIA. George J. Hollenberg, La Verne College, La Verne, Calif.—A species of Dermocorynus, very close to D. Montagnei, the type species, has been found along the coast of Southern California. The latter seems not to have been collected since first described in 1867. Two new members of the Champiaceae are close to Gastroclonium, from which they both differ in the regular production of polyspores.

Some watermolds found in southern califor-NIA. James V. Harvey, San Bernardino Valley Junior College, San Bernardino, Calif.—Since December, 1935, 345 samples of water or soil have been taken in California, Arizona, and Utah for the purpose of isolating species of the Saprolegniaceae. No Saprolegniaceous species was obtained from fifty samples from the Arizona-Utah region, but Allomyces arbuscula Butler was taken from Totem Pole Wash in Monument Valley. Pythium species, mostly P. deBaryanum, various Zygomycetes and Ascomycetes, as well as Fungi Imperfecti and Algae were commonly isolated over the entire area. From the 295 collections made in California the following watermolds have been isolated, the number of times each organism was isolated following its name: Saprolegnia ferax, form I, Minden, 49; S. ferax, form II, Minden, 2; a new variety of S. delica Coker, 5; S. diclina Humphrey, 1; two undescribed, non-sexual species of Saprolegnia, 3, and 20 times, respectively; Achlya flagellata Coker, 3; A. caroliniana Coker, 7; A. sp., resembling both A. flagellata and A. caroliniana, 2; two types of Achlya without sexual reproduction, 11; Dictyuchus sterile Coker, 17; Dictyuchus sp., 1; Aphanomyces laevis DeBary, 19; Brevilengia megasperma Harvey, 2; Geolegnia inflata Coker, 1. The morphological features of each species isolated were illustrated with several lantern slides of line drawings.

INDUCTION OF POLYPLOIDY AND STERILITY IN AM-PHIDIPLOIDS INDUCED BY HETERO-AUXIN TREATMENT. Walter H. Greenleaf, University of California, Berkeley, Calif. (Introduced by R. E. Clausen.)-By means of the decapitation-callus method, using 1 per cent by weight of hetero-auxin (indole-3-acetic acid) in lanolin, 1,973 callus shoots produced by F<sub>1</sub> hybrids of N. sylvestris-tomentosiformis and by N. sylvestris-tomentosa, were classified. Of these, 14.7 per cent were tetraploids, about 1 per cent octoploids, and about 0.1 per cent otherwise unbalanced chromosomally. Autotetraploids of N. tomentosiformis, N. tomentosa, N. sylvestris, and tetraploids of N. glauca shoots were similarly obtained. The allopolyploids N. sylvestris-tomentosiformis and N. sylvestris-tomentosa proved completely female sterile, though the pollen was good. Cytological study indicates that this sterility is due to early degeneration of the embryo sacs. The pollen tubes grow readilv. Megasporogenesis is regular, so the degeneration cannot be ascribed to incomplete chromosomal complements resulting from disturbed chromosomal relations. The degeneration phenomena, essentially alike for both amphidiploids, are similar to that of the F<sub>1</sub> hybrid, which, however, exhibits abnormal meiosis. It is possible that D. Kostoff's fertile amphidiploid sylvestris-tomentosiformis, obtained by crossing N. sylvestris-tomentosiformis  $\times$  N. sylvestris X N. tomentosiformis, is a somewhat altered amphidiploid, possibly occurring on account of pairing in the F<sub>1</sub> hybrid sylvestris-tomentosiformis.

FLOWER COLOR-INHERITANCE IN THE CARNATION. Gustav A. L. Mehlquist, University of California, Berkeley, Calif. (Introduced by E. B. Babcock.)— Six independent factors concerned with self-colors have been identified. Their actions may be summarized as follows: Y controls the production of yellow anthoxanthin. I, epistatic to Y, controls the production of ivory anthoxanthin. A is the basic anthocyanin factor. It is normally effective only in the presence of both Y and I. Partial anthocyanin is possible in the absence of I, the resultant color varying from orange to maroon depending on what specific anthocyanin factors are present. S controls the production of scarlet-red anthocyanin; its recessive allele s produces dilute red or salmon. R controls the production of crimson-red anthocyanin; its recessive allele r permits the production of scarlet-red anthocyanin only. M modifies the red anthocyanin colors to the corresponding colors of the magenta series. It has no effect in the acyanic series.

(The following four papers were presented at a joint session with the Ecological Society of America, Western Section, in a symposium on "RECENT CONTRIBUTIONS OF BOTANY AND ECOLOGY TO SOCIETY.")

RECENT ACHIEVEMENTS IN PLANT BREEDING. E. B. Babcock, University of California, Berkeley, Calif.—Progress in the application of the Mendelian principles in plant breeding was reviewed under the following heads. (a) Breeding new varieties to order. (b) Utilizing hybrid vigor. (c) Breeding for disease resistance. The development of cytogenetics and

some important applications were discussed as follows: (a) Interspecific hybridization and amphidiploidy in plant evolution and breeding. (b) Artificial doubling of the chromosomes and the utilization of interspecific hybrids. (c) Using monosomics and trisomics in the mapping of chromosomes and its bearing on the breeding of the future. Improvements in technique involve, (a) Applied statistics, field plot technique, etc. (b) Determining chromosome numbers. (c) Speeding up normally slow plants.

SOME RECENT CONTRIBUTIONS OF ANIMAL ECOLOGY TO HUMAN WELFARE. Tracy I. Storer, University of California, Davis, Calif.—Problems of human welfare as affected by animals are numerous in the fields of agriculture, fish and game, commercial fisheries, forestry, fur production, public health, and recreation. Man has long sought to regulate, use, or destroy animals to his own benefit, though often without an accurate understanding of the interrelationships between animals and their environments. Qualitative information available has proved inadequate and is gradually being supplemented or replaced by quantitative data. Ecological relations of animals are perhaps the most complex phenomena of science, rivalling those of sociology, because of the multitude of interacting and often uncontrollable variables. Present day research in animal ecology, much of it with economic objectives, is gradually providing important material that will eventually portray truthfully the interrelations that occur in nature. Examples discussed included population studies in species with both stable and fluctuating numbers; effects of irrigation and of drainage on wild life; manipulation of cover as affecting game and non-game species; some newer knowledge of predator-prey relationships as the basis for more rational management: and some results proceeding from more detailed knowledge of rodent vectors of disease as affecting the health of man.

MYCOLOGY IN THE SERVICE OF MANKIND. E. P. Meinecke, U. S. Forest Service, San Francisco, Calif.—From oldest antiquity man has used fungi in some form for a variety of purposes. With the crystallization of knowledge about fungi in modern mycology and the refinement in scientific and industrial technique came an ever increasing utilization. It was in particular the development of the pure culture that made progress possible. The cultivation of fungi for food, highly developed on an empirical basis by the Chinese and Japanese, has grown into a large industry that works with pure strains and laboratory methods. Pure cultures are employed in the manufacture of such cheeses as Roquefort and Gorgonzola. Yeast in pure culture has become a popular treatment in certain nutritional diseases of man. The most important services rendered by mycology lie in the field of indirect uses in industries. With very few exceptions this is the only field of applied botany in which a plant is deliberately set to work to produce by-products rather than to produce plant tissue, flowers, or fruit. The control of harmful fungi, based mainly on a clearer understanding of fungous ecology and physiology has helped to make modern agriculture. In forestry, in horticulture, in the grain-field, the orchard and the greenhouse, success hinges upon a well-understood, carefully planned and executed control of fungous diseases. Research on the manifold mycoses has cleared up many of the formerly mysterious diseases of man and animals.

SOME RECENT CONTRIBUTIONS OF PLANT ECOLOGY TO HUMAN WELFARE. H. L. Shantz, U.S. Forest Service, Washington, D. C .- America has recently been aroused by the realization that cultivated fields, forests, grasslands, desert shrub areas, swamps, lakes, and rivers have been despoiled by careless overuse and abuse. These lands and waters must be brought back to a more normal and naturally productive state. The ecological approach is basic to all management of these areas. This is especially true of raw land use and of the management of forests, grasslands, deserts, swamps, lakes and streams. Farmlands and pastures likewise are receiving special attention from ecologists. Ecologists, by using the synthetic method on data obtained earlier by analytical investigations, are aiding in solving problems of soil erosion; grazing and range management; rebuilding depleted lands and waters to productive levels; control of weeds and succession of annual plants on areas under use; and general land, stream, and lake management. These are only a few of the practical problems confronting the plant ecologists.

THE EFFECT OF ANAEROBIC CONDITIONS ON MITOSIS IN SEEDLINGS OF HORDEUM. G. L. Stebbins, Jr., and Lotti Steinitz, University of California, Berkeley, Calif.—Actively growing seedlings of Hordeum vulgare were subjected to an atmosphere nearly free from oxygen by the use of nitrogen and pyrogallol. This caused immediate cessation of growth and of mitotic divisions. After three to four days mitosis was resumed under anaerobic conditions for a few days. The dividing tissue under these conditions shows the following differences from normal, control material. (1) The resting nuclei are smaller; (2) the staining is more intense, particularly of nucleoli and heterochromatic material, both in acetocarmine smears and in sections stained with gentian violet; (3) the chromosomes are much more contracted and tend to become clumped together at metaphase in both smear and sectioned preparations; (4) the chromosomes are often scattered through the cell at anaphase. Under prolonged anaerobic conditions the nuclear membrane breaks down, nuclear material becoming extruded into the cytoplasm. Some seedlings treated for four and five days recovered upon being returned to normal conditions, and after one to two days mitosis was normal in them.

STRUCTURE AND GROWTH OF THE SHOOT APEX OF CYCAS REVOLUTA AND ZAMIA FLORIDANA. Adriance S. Foster, University of California, Berkeley, Calif.—For the complete paper, see Amer. Jour. Bot. 26: 372–385.

THE USE OF AN ALTERNATING "TRANSLONGITOME"
IN MAKING AND INTERPRETING SERIAL SECTIONS.

D. M. Crooks, University of Arizona, Tucson, Ariz. -An alternating two-plane cutting attachment known as a "Translongitome" has been developed for use in an ordinary rotary or sliding microtome. which will cut alternate cross and longitudinal sections from the same block of tissue so that the alternate sections come from the microtome knife in one continuous ribbon. This ribbon, which has both cross and longitudinal cuts from the same block, may be mounted and examined on the same slide. If one follows a series of these sections, it is possible to observe a particular bundle or structure in cross section and also see the same bundle in longitudinal section. As any particular bundle in cross section comes to the cutting face of the longitudinal section, it is possible to determine the thickness of the bundle by counting the number of longitudinal sections which are required to cut through the entire thickness of the bundle and multiplying by the thickness of the section. It is necessary to set the microtome at onehalf the desired thickness for sections are cut from either face only on alternating strokes of the microtome. The translongitome is mechanically simple, and a manufacturing concern will soon make it available in a non-ferrous metal to those interested in its

A PLANT GROWTH INHIBITOR AND PLANT GROWTH INHIBITION. Wm. S. Stewart, California Institute of Technology, Pasadena, Calif.—When eight-day-old radish cotyledons are ether extracted according to the method given by Van Overbeek for auxin extraction, a non-toxic substance is obtained which is capable of causing plant growth inhibition. In the Avena coleoptile the inhibition is manifested as a positive growth curvature within 90 minutes from the time of application of the extract. The relation between the concentration of the inhibitor and the degrees of positive curvature is linear between 3 and 13 degrees. This allows the use of a modified Avena test as a quantitative biological assay for inhibitor substance. Using this method it was found: (1) That inhibitor was transported non-polarly in the radish and Avena plant; (2) that during the growth of the foliage leaves inhibitor disappeared and was replaced by auxin; (3) that inhibitor can be readily hydrolysed to form auxin, probably the auxin being indole-acetic-acid. Other experiments show that the positive Avena curvatures may be explained on a basis of the decreased growth rate of the inhibited plants.

A STUDY OF THE PERISPORIACEAE, CAPNODIACEAE, AND SOME OTHER "SOOTY MOLDS" FROM CALIFORNIA. Vera M. Miller, University of California, Berkeley, Calif.—"Sooty molds" form a superficial dark film of mycelium over the outer surfaces of plants. Many of these fungi are epiphytes and obtain their nutrition from the moisture of the air and from "honey dew" secreted by insects. Economically "sooty molds" are of slight importance. A number of "sooty molds" have been collected in the San Francisco Bay region where climatic conditions are particularly favorable to their growth. The perisporiaceous and

capnodiaceous "sooty molds" occurring in California were enumerated, with particular attention being given to previously undescribed species. A new genus, seven new species, and a new combination were proposed. Twenty-nine host plants were listed, some of the plants being attacked by as many as five species of "sooty molds." Twenty-eight "sooty mold" fungi are recorded. Several of them occur on more than one host, one of them appearing on six different plants—on three broad-leaved trees, on two ferns, and on redwood.

Effect of shade on flowering of sugar beets. Eubanks Carsner, U.S. Department of Agriculture, Riverside, Calif.—Fall planted beets at Riverside, California, bolted more extensively if artificially shaded. Vertical shades which protected the plants and the soil around them from direct sunlight, and horizontal shades which allowed the leaves to be exposed but shaded the surrounding soil, both resulted in increasing the percentage of bolters over that in unshaded checks. Shading the soil keeps it cooler. The temperature of the beet roots is nearly the same as that of the surrounding soil. Growth of beets at low temperatures is conducive to induction of flowering. Early planting gives nearly the same effect on bolting as does artificial shade, because a large leaf area developed in the fall effectively shades the soil during the winter. In addition to the indirect relation of leaf area to thermal induction of flowering there may be a relation between leaf area and induction by light.

Aposporic development in crepis. G. L. Stebbins, Jr., and J. A. Jenkins, University of California, Berkeley, Calif.—Reproduction in the polyploid forms of the North American species of Crepis is by means of somatic apospory followed by diploid parthenogenesis. Meiosis in the pollen mother cells of three apomicts of C. occidentalis and C. intermedia is nearly normal except for the occurrence of multivalents, and of bridge-fragment configurations at first anaphase. In an apomict of C. acuminata the pollen mother cells degenerate in mid-prophase of meiosis so no pollen is formed. The various apomicts differ in the stage of development at which apospory begins and in the frequency with which it occurs, but in all but one of those studied normal embryo sacs were formed in some of the ovules. Apomixis is therefore chiefly facultative and resembles closely the type already known in Hieracium subg. Pilosella.

INHERITANCE OF RED SEED COAT COLOR IN COM-MON BEANS. Francis L. Smith, University of California, Berkeley, Calif. (Introduced by E. B. Babcock.)—In a search for red seed coat color genes and modifiers which could later be used in a program of breeding improvement, a number of independent genes were found. Results of numerous crosses and the effects of the genes involved were reported. Many of the results were difficult to interpret.

ANATOMY OF VASCULAR TISSUES. Katherine Esau, University of California, Davis, Calif.

Translocation of viruses in plants. C. W. Bennett, U. S. Department of Agriculture, Riverside, Calif.

MOVEMENT AND DISTRIBUTION OF RADIOACTIVE ELEMENTS IN PLANTS. D. R. Hoagland and J. P. Bennett, University of California, Berkeley, Calif.

THE MECHANISM OF MOVEMENT OF ORGANIC MATERIALS IN PLANTS. (a) PROTOPLASMIC STREAMING. O. F. Curtis, Cornell University, Ithaca, New York. (Read by A. S. Crafts.) (b) ACTIVATED DIFFUSION. T. G. Mason, Cotton Research Station, Trinidad, British West Indies. (c) PRESSURE FLOW. A. S. Crafts, University of California, Davis, Calif.

The six papers listed above were presented before a joint session of the Botanical Society and the Western Section of the American Society of Plant Physiologists in a symposium on "The Translocation of Solutes in Plants." The abstracts are in the hands of the secretary of the latter society.

(The following five papers were presented in a symposium on "Native Plants of Western North America Offering Exceptional Material for Botanical Research.")

THE LOWER PLANTS, ESPECIALLY ALGAE. Gilbert M. Smith. Stanford University, Calif.—Intensive investigation of small ponds, reservoirs, and streams offer excellent opportunities to the algologist interested in fresh water forms, though that flora is less rich in the western United States than in some of the regions where numerous lakes provide suitable habitats for the smaller fresh water algae. The outstanding opportunity seems to lie in the investigation of the vegetative features of the organism responsible for "red snow," but few have seen the rarer phenomenon, "green snow." The latter should be studied. Careful collecting and study of the marine algae should yield valuable information concerning the life histories and range of the smaller, less known species. The work of G. J. Hollenberg demonstrates the fruitfulness of this type of painstaking work. Collectors studying the Heterocontae and Chrysophyceae should use hard glass containers in order to avoid disintegration of delicate algae, many of which are very sensitive to minute traces of substances contained in soft glass.

OPPORTUNITIES FOR RESEARCH IN MYCOLOGY IN CALIFORNIA. Lee Bonar, University of California, Berkeley, Calif.—Owing to the wide range of climatic conditions and to the relationship of the fungi to the higher plants of the region, the mycoflora of the state is rich in variety and number of species and in the wide range of different types. A comparison of the status of our present knowledge of the seed plants with that of our mycoflora emphasizes the need for systematic collection and study of the fungi. The disposition of collections of early workers was such that few are available locally. It is important that we build up collections of western fungi in herbaria in our area. Monographic studies of certain groups show that many species are peculiar to our region. Many other groups are well represented in the state and offer exceptional material for investigation. The study of incompletely collected areas entails long continued, intensive, and repeated collections. The fungi of the arid regions should be studied and compared with those of similar habitats in other parts of the world. Fungi parasitizing introduced seed plants should be studied. Good opportunities exist in the field of cultural, inoculation, and morphogenesis studies.

PLANTS OF THE SOUTHWEST OFFERING OPPORTU-NITY FOR BOTANICAL RESEARCH. D. M. Crooks, University of Arizona, Tucson, Ariz.—The range grasses offer many opportunities for anatomical work in interpreting their life histories relative to environment and grazing practices. Marked variations in different species are indicated by preliminary studies and the relation of establishment of adventitious root systems to climatic conditions needs study. Detailed studies of life histories of certain range weeds will be useful in determining methods of control. Studies of the floral development in Burroweed, in which flower primordia initiated in August mature seed in sixty days, serve as a guide and beginning point in this type of work. The problem of the lack of nodule development on the roots of desert leguminous plants should be investigated from a morphological viewpoint. Morphological studies should be undertaken in connection with the form of growth, gross development, and ontogeny of parts of native plants exhibiting habits very different from those of plants growing in more mesic conditions. Six main types of desert plants invite this sort of investigation. They are: (1) those with succulent stems; (2) thorny shrubs with reduced leaves and specialized stems; (3) chaparral type of shrubs; (4) semiherbaceous perennials with peculiar types of secondary root development; (5) the fleshy storage root type; (6) thick stemmed monocotyledons.

CYTOGENETICS, INTERSPECIFIC RELATIONSHIPS, AND DISTRIBUTION IN THE WESTERN FLORA. G. L. Stebbins, Jr., University of California, Berkeley, Calif.—The application of cytogenetic techniques to the species problem has made possible the recognition of several cytogenetic patterns which are correlated with patterns of morphological variation. All of these occur in genera in the western flora. The types are: (1) Rassenkreis. The genus contains relatively few species, each with the same number of chromosomes, but each species consists of several interfertile subspecies or geographic varieties. (2) The homoploid complex. Genera of large numbers of species separated by slight morphological differences, but more or less intersterile in spite of uniform chromosome number. (3) The aneuploid series. Closely related species have different basic chromosome numbers; otherwise like (2). (4) The polyploid complex. Species of the group have different chromosome numbers that are multiples of the same basic number. Diploid species are distinct from each other, but are connected by a series of auto- and allopolyploid derivatives. (5) The agamic complex. Similar to (4) but the polyploids partially or wholly apomictic. (6) The segmental interchange complex. All species with the same chromosome number but with different segmental arrangements, with races that form rings or chains at meiosis common. Hybrids among these races may retain their constancy by means of a system of balanced lethals. A study of a number of such groups in the western flora should contribute materially toward an understanding of its history.

EXPERIMENTAL STUDIES ON RELATIONSHIPS OF WESTERN PLANTS. William M. Hiesey, Carnegie Institution of Washington, Stanford University, Calif. —A review of the transplant work carried on by the Carnegie Institution staff at the three stations located at Stanford University, at Mather, and at Timberline in California, indicates the possibilities in this field. The West, with its varied topography and climates, offers exceptional opportunity for much-needed investigations on the relationship between plants and their environment. Analyses of the composition of ecotypes would now be especially valuable to complete our understanding of species composition. A field offering much promise is the comparative anatomical and physiological study of ecotypes of one species, or of closely related species.

THE PROCERI PENSTEMONS-A PROBLEM IN CYTO-TAXONOMY AND DISTRIBUTION. David D. Keck, Carnegie Institution of Washington, Stanford University, Calif.—Penstemon, of the Scrophulariaceae, is a genus composed of many sections and subsections. The subsection Proceri contains some of the most complex taxonomic problems in the genus. The great number of forms which have been ecologically differentiated within it is now better understood as a result of a cytological survey of many of the species and races and from transplant experiments. Apparently the center of origin of the Proceri Penstemon species is in the Columbia River basin, from which a radiation of forms has occurred in all directions. Most of the species are diploid (n = 8), but there are obviously related tetraploid and hexaploid species, which are apparently derivatives of the diploids and occupy different habitats from them.

The limits of the plant kingdom. Herbert F. Copeland, Sacramento Junior College, Sacramento, Calif.—The proposal made recently (The Kingdoms of Organisms, Quart. Rev. of Biol. 13: 383–420, 1938), to recognize two kingdoms of organisms, designated respectively as Monera and Protista, in addition to the Plantae and Animalia, was discussed. A summary of comments and criticism communicated to the author indicated an almost equal division between support and opposition to the proposal.

The taxonomy and geographic distribution of the genus erysimum in north america. George B. Rossbach, Stanford University, Calif.—The genus Erysimum of the family Cruciferae is a variable group occupying sterile, sandy, or gravelly habitats through much of the northern hemisphere. Fifteen species and seven varieties, some of which include taxonomic complexes, are recognized. Geographical distributions of entities may be circumboreal, or in North America, may comprise such large areas as the higher mountains of the western United States,

or the Great Plains. Others may be restricted to local areas, such as certain coastal parts of Quebec and Newfoundland; the higher Olympic Mountains of Washington; the San Francisco Peninsula in California; the marine sand deposits on the southern edge of the Santa Cruz Mountains; small areas of coastal dunes; or the Channel Islands off the coast of southern California.

Thomas howell, the pioneer botanist of oregon. Albert R. Sweetser, University of Oregon, Eu-

gene, Ore. (Read by title.)

GEOGRAPHICAL DISTRIBUTION AND ECOLOGY OF SOME NORTH AMERICAN SPECIES OF DESCURAINIA, AND THEIR BEARING ON THEIR TAXONOMY. LeRoy E. Detling, University of Oregon, Eugene, Ore.—Owing to the wide range and adaptation to greatly varying habitats several species of Descurainia in North America offer exceptional opportunities for studying the selective effect of habitat on the species. Each climatic niche in western North America is occupied by one particular form of the species. Each form so limited by its environment is considered a subspecies. In D. pinnata subspecies have developed in: (a) South Atlantic and Gulf coasts; (b) plateau regions of the southwestern states; (c) deserts of southwestern United States and adjacent Mexico; (d) southern California coastal region; (e) the northern borders of the Great Basin; (f) the plains of the north central states and Canada; (g) the central Rocky Mountains; (h) Columbia Plateau; (i) desert region of Wyoming and Utah. The subspecies of D. Richardsonii occur in moister, cooler habitats located in: (a) Canadian plains; (b) central Rocky Mountains; (c) mountains to the east, north, and west of the Great Basin; (d) southern Rocky Mountains. D. obtusa consists of three subspecies occurring in: (a) juniper belt of the Colorado Plateau; (b) deserts of the southwestern United States; (c) pine forests included within the range of the two above.

THE TAXONOMIC SIGNIFICANCE OF THE NECTARY SCALE IN RANUNCULUS. Lyman Benson, University of Arizona, Tucson, Ariz.—Five types of nectary scales are found in the North American species of Ranunculus. Some types are characteristic of whole sections. (1) Simple scales, free laterally and overarching the gland: subg. Euranunculus sect. Chrysanthe (except R. recurvatus); most species of sect. Echinella; subg. Cyrtorhyncha, sect. Halodes; subg. Ceratocephalus. (2) Pocket type, attached laterally as well as basally: subg. Euranunculus sect. Flammula and Epirotes; subg. Cyrtorhyncha sect. Arcteranthis and Pseudaphanostemma; subg. Batrachium; subg. Pallasiantha; subg. Coptidium; subg. Ficaria. (3) Low transverse ridge neither forming a pocket nor overarching gland: subg. Cyrtorhyncha sect. Eucyrtorhyncha; subg. Oxygraphis. (4) Transverse ridge with lateral ends produced into flaps extending distally and attached to the surface of the petal, the flaps sometimes meeting and then surrounding the gland: subg. Euranunculus sect. Hecatonia (some species); subg. Crymodes. (5) The scale bearing the nectary in a pocket on its own ventral surface: R. flabellaris (delphinifolius), and sometimes R. Purshii. Special peculiarities, such as the ciliate scales of R. cardiophyllus and R. arizonicus, are helpful in determining the limits of species.

STRUCTURAL HYBRIDITY IN PAEONIA CALIFORNICA AND P. BROWNII. G. L. Stebbins, Jr., University of California, Berkeley, Calif. (For a paper dealing with these species see Madrono 4: 252-260. 1938.)

WESTERN AMERICAN ACHILLEA AS DEFINED BY EX-PERIMENTAL TAXONOMY. Jens Clausen, Carnegie Institution of Washington, Stanford University, Calif. -The Western American Achilleas of the millefolium complex are native, not introduced. This complex, which encircles the northern hemisphere, has probably attained its greatest evolutionary differentiation in the Western United States. It has here evolved ecotypes adapted to climates ranging from the maritime to the arctic-alpine and the dry Great Basin conditions. Contrary to the general assumption, our West American Achilleas are specifically distinct from the Eurasian Achillea millefolium. We have at least two indigenous species. One is the hexaploid Achillea borealis Bong. (n = 27), which occurs along the Pacific Coast of North America from Alaska to Lower California, occupying also the Coast Ranges of California. The other is the tetraploid A. lanulosa Nutt. (n = 18), which occurs from low to alpine altitudes in the Sierra Nevada and the Cascades and east through the Great Basin to the Rockies. Each of the two contains several morphologically very diversified ecotypes, which react very differently when transplanted to diverse altitudes. The Northern European A. millefolium L. is hexaploid like borealis but does not hybridize with it.

Hybrids of the california flora. Carl B. Wolf, Rancho Santa Ana Botanic Garden, Anaheim, Calif.

—A large number of supposed hybrids have been reported as forming part of the California flora but few have been tested by cytological or breeding experiments to determine their exact status. It is suggested that some of the puzzling complexes in our flora might be cleared up by critical field observations and garden experimentation. Collectors should try to take representative samples in a variable population instead of selecting, somewhat unintentionally, the plants that make the most convenient herbarium specimens.

PROBLEMS OF DISTRIBUTION AND VARIATION IN THE GENUS ZYGADENUS. Oliver S. Walsh, University of California, Berkeley, Calif.—Great variations occur in the gross morphology of Zygadenus under different environmental conditions. Wet habitats promote woody growth, large leaves, large flowers; dry situations tend to encourage smaller plants, leaves, and flowers, succulent bulbs, and a more solitary growth habit.

THE GENUS MONOLOPIA: A PROBLEM IN DISTRIBUTION AND DIVERGENCE. Ethel Crum, University of California, Berkeley, Calif.—Monolopia, belonging to the tribe Helenieae, is endemic in California and,

excluding *Pseudobahia*, consists of four species having their center of distribution in the south Coast Ranges. *Monolopia* seems to be the resultant of three lines of reduction common in the *Helenieae*: (1) loss of pappus; (2) loss of receptacular bracts; (3) reduction in number of involucral bracts. A secondary

line of divergence manifests itself in the development of a slightly bilabiate ray corolla. Important tendencies toward divergence within the genus itself are: union of the involucral bracts; flattening of the achenes. One of the four species included is a previously undescribed entity.

# ALCOHOL EXTRACTION OF GROWTH HORMONE FROM PLANT TISSUE 1

George S. Avery, Jr.

Two general methods are in use for assaying the growth hormone in plant tissues—the diffusion method (Went, 1928) and the extraction method (Thimann, 1934; Laibach and Meyer, 1935; Boysen Jensen, 1937; du Buy, 1938; Overbeek, 1938a). The former makes it possible to measure the amount of hormone that will diffuse from tissue into agar, and this has been interpreted as indicating the relative concentration of hormone in the tissue. The extraction method, on the other hand, makes possible an assay of the total quantity of hormone in the tissue or organ being tested. Both methods have their place, according to the problem being investigated; but the latter, as a truly quantitative method, marks an important advance in plant hormone studies.

Aside from the extraction method used by Laibach and Meyer (1935), all others utilize chloroform or ether as the solvent. In contrast to the chloroform and ether extraction methods, Laibach and Meyer boiled plant tissue in acidulated 96 per cent alcohol in order to extract the plant growth hormone. For purposes of testing, the concentrated extract was mixed with lanolin and applied unilaterally to Avena coleoptiles (not decapitated).

The extra time involved in extraction of growth hormones from impervious materials, such as seeds, and the possible loss of heat-labile growth promoting hormones by the Laibach and Meyer method, or the ether or chloroform destruction of them by the other procedures, led to the development of a method for their rapid extraction from ground plant material with cold absolute alcohol. Possible oxidation reactions destructive to growth hormones are prevented by the use of alcohol and the immediate grinding of the tissues. The method is based primarily upon extraction methods which are known to remove many pigments rapidly and completely from plant material (Strain, 1938). The procedure outlined here has been used for the past eight months; it gives reproducible and reliable results. Thus far it has been used for the extraction of growth hormone from maize endosperms and dormant maize seeds. The following is an outline of the method:

A. MATERIAL AND PREPARATION.—Ten maize seeds (about 3 grams) plus an approximately equal weight of sand2 plus five to ten times seed weight of absolute ethanol are ground in a glass mortar until no particles are visible. N/10 HCl may be added to the amount of one-fifth the volume of ethanol, though this apparently has no per-

<sup>1</sup> Received for publication April 17, 1939.

It is a pleasure to express my appreciation to Dr. H. H. Strain of the Carnegie Institution, Stanford University, California, for his suggestion of the method and his inter-

est in its development.

<sup>2</sup> Sand. Treat with 30 per cent NaOH two hours. Wash thoroughly with water. Wash with concentrated HCl overnight. Wash in running tap water 10 hours. Allow to stand in water and test with litmus. Wash with distilled water. Drain and dry before using as indicated above.

ceptible effect on extractions from dormant seeds. A single maize seed may be extracted by the same method, using correspondingly smaller portions of sand, ethanol, etc.

B. FILTRATION.—The ground mass is placed on a filter of Hyflo Super Cel (Johns-Manville) prepared as indicated in figure 1, using a funnel just large enough so that all the

Fig. 1. Diagram showing round bottom flask and funnel prepared for filtering tissue ground with ethanol.

ground material can be added at once. Suction is then applied. The mortar and pestle are washed with two 10 cc. portions of ethanol, pouring each through the filter, using suction. (Note: When tissue ground with ethanol is poured into filter, distribute evenly on the sand and allow to stand for a short time before starting suction.)

C. EVAPORATION OF FILTRATE.—After filtering, remove the stopper with funnel (apparatus indicated in fig. 1), and insert a one-hole stopper with glass tubing, for suction attachment. Evaporate filtrate at reduced pressure with water bath at 50-55°C. Temperatures up to 80-90°C. have not proven destructive to growth hormones extracted from maize seed, hence in this instance it is not important to keep temperatures low. In extracts of many materials, however, it would seem best to keep the temperature low in case there should be volatile or decomposable growth hormones present.

D. GROWTH HORMONE-AGAR MIXTURE.—To the dry residue obtained by evaporation of alcohol, add 20 cc. of water,3 and shake well. (For small amounts of tissue it may be necessary to add as little as 2-4 cc. of water; if so, add 2 cc. of recently distilled ether, shake well, and then warm in 50-55°C. water bath to evaporate ether. The addition of ether reduces the yield of growth hormone, hence it is better wherever possible to use larger amounts of tissue and take up the dry residue in water only.) Remove 1 cc. of water and dilute this with 1 cc. hot 3 per cent agar. The agar should be washed and allowed to soak in several changes of distilled water for four or five days before use, then dried, and made up at required percentages (1.5 and 3 per cent).

E. Dilution.—Use one part of the agar-water mixture (containing growth hormone) from D with one or more parts of 1.5 per cent agar, depending upon the dilution desired for testing. Several different dilutions should be prepared and tested to make certain that the test is within the "proportionality range" of the Avena test plants (see table 1). If the dilutions do not give curvatures in this range, the Avena tests should be repeated until the proper dilutions are determined for making possible a quantita-

tive assay.

F. CASTING OF AGAR PLATES .- Pipette the hot agar, containing given dilutions of growth hormone extract, into molds  $8 \times 10.7 \times 1.5$  mm. When the agar has set, cut into

<sup>3</sup> See table 1; 20 cc. is the proper amount in this instance. Actually, the dilution must be such that the hormone tests will be in the "proportionality range."

[The Journal for October (26: 567-678) was issued October 3, 1939.] AMERICAN JOURNAL OF BOTANY, Vol. 26, No. 9, November, 1939.

<sup>&</sup>quot;The endosperms are removed from test plants 16 hours before use. The coleoptiles are decapitated, and immediate unilateral application of agar blocks follows. Shadow photographs of curvatures are taken after five hours.

12 equal blocks for application to decapitated Avena coleoptiles.

Each experiment is run in two or more series, as in table 1, to insure an adequate check on the accuracy of the determinations. Typical results, obtained from the extraction of endosperms (embryos removed) of dormant grains of maize, variety Canada Flint (obtained through the courtesy of Dr. Ralph Singleton of the Connecticut Agricultural Experiment Station), are recorded in table 1. The Avena test plants were A. sativa, var. Victory (Svalöv).

Computation of results.—The total hormone content of the endosperms may be expressed in terms of total degrees curvature of *Avena* test plants, computed as follows:

The dimensions of each small rectangular plate of agar cast in the above-mentioned mold are  $8 \times 10.7 \times 1.5$  mm. (Dolk and Thimann, 1932), hence the volume is 128.4 cubic millimeters. Each piece  $8 \times 10.7 \times 1.5$  mm. is cut into 12 small blocks of equal size, hence whatever growth hormone is contained in the agar plate is capable of producing a given curvature in each of twelve test plants. In the case of method III, table 1, an average curvature of 15.2° was obtained. Tests on further dilutions showed the response

Table 2. Hormone content of dormant endosperms, variety Canada Flint. Each figure representing Avena curvature at the different dilutions in series A, B, etc., is the average of twelve test plants. Each series represents the extraction of one endosperm. Avena test laboratory maintained at 25°C, and 88-90 per cent humidity.

<sup>&</sup>lt;sup>a</sup> Calculations based on 160 cc. dilution.

to be in the proportionality range. Hence, the computation is as follows:  $15.2\times12=182.4=$  total degrees curvature obtainable from 128.4 cubic millimeters of agar containing a given concentration of growth hormone.— The total volume of agar in this experiment is 160 cc., or 160,000 cubic millimeters.— $160,000\div128.4=1,246$ . That is, 160 cc. of agar would, if east in molds as above, make 1,246 agar plates  $8\times10.7\times1.5$  mm.—Hence 1,246  $\times$  182.4 = 227,270 total degrees curvature for ten endosperms, or 22,727 degrees curvature per endosperm. This means that the growth hormone present in each dormant endosperm of Canada Flint maize, if extracted by the method described, is capable of producing a total of approximately 22,727 degrees curvature in a suitable number of Avena test plants ("deseeded" method).

The above computation of results has the same basis as the plant unit of Dolk and Thimann (1932), where one plant unit is that amount of growth hormone which, when applied in an agar block of ca. 10 cmm. to a test plant, causes 1° curvature. The plant unit, however, is based on Went's "standard" method; curvatures in the "deseeded" method are approximately four times as great as in the "standard" method (Avery, Creighton, Hock, 1939).

When put on a weight basis, the results of the different methods may be readily compared (table 3). Method III gives the best agreement between the extractions of one and ten endosperms.

Discussion.—Skoog's "deseeded" method has been used here rather than the "standard" method of Went, because lower concentrations give Avena curvatures of greater magnitude, also because Koningsberger and Verkaaik (1938) report less fluctuation in day to day tests by this method.

It will be noted that the yield in method I is lower than in methods II and III. The loss in method I may be due partly to the use of ether and partly to adherence to the walls of the flask (because of the small volume of water and ether). In any case, it is clear that taking the dry residue up in a large amount of water is effective in increasing the yield. If necessary to use a small amount of water because of a small amount of tissue being extracted, as indicated in step "D," the flasks should be not more than 50 or 100 cc. capacity; this will reduce the loss to the walls of the flask.

If the residues are fatty or gummy, as they are in the case of maize seeds, the growth hormone may go into solution slowly, even when a large volume of water is used. Small glass beads or coarse quartz sand added to the alcohol about the time that fats start to separate, during the evaporation (step "C"), increases the surface so that the extraction of the final dry residue with water is more complete.

Acidulation of the alcohol used in extraction in step "A" increases somewhat the yield of growth hormone (from dormant seeds), particularly in the case of the extraction of one endosperm. This is very likely due more to the addition of water than to the addition of acid. Van Overbeek (1938a) has reported a higher yield (than that reported here) of hormone from maize by water extraction. Cholodny (1935) found no hormone when extracting maize seeds, etc., with alcohol, whereas water extraction gave positive results. Using the alcohol method described here, Avery, Creighton, and Hock (1938) have reported preliminary results comparable with certain of those of Cholodny, in that endosperm after a few hours hydration gave a greater yield of growth hormone than the dry endosperm.

An extensive comparative study of the numerous different extraction methods described in the literature will soon be completed.

#### SUMMARY

A method is described for the rapid extraction of all alcohol soluble growth hormone from ground plant tissues, using absolute ethanol. The method does not involve use of ether or chloroform, and extracts can be prepared quickly for testing by standard procedures, such as Skoog's "deseeded" method or the "standard" method of Went. To date exhaustive tests have been made only on maize endosperms and entire maize seeds.

Connecticut College, New London, Connecticut

# A DEVELOPMENTAL ANALYSIS OF HETEROSIS IN LYCOPERSICON. II. THE ROLE OF THE APICAL MERISTEM IN HETEROSIS <sup>1</sup>

William Gordon Whaley

DIRECT MEASUREMENTS were made of the volumes of the apical meristems of the plants described in Part I of this paper (Whaley, 1939) in an attempt to test the validity of Ashby's hypothesis (1930, 1932, 1937) concerning the importance of the mass of "original meristematic capital" in the development of hybrid vigor. Cell and nuclear sizes in the meristems were studied in some detail to determine what correlation, if any, could be found in these embryonic masses between morphological changes during development and the behavior of the plant as a whole.

Methods.—Each time samples were taken for weight determinations, ten main stem tips of each type were collected. These were immediately killed in chrom-acetic-formaldehyde solution and imbedded in paraffin. Serial longitudinal sections, 6 microns in thickness, were cut through a stem tip of each type from each sample. Care was taken to preserve the sections in proper serial sequence. These were mounted and stained with a triple stain of Delafield's hematoxylin, safranin, and light green. Using a Leitz projection microscope, a series of drawings of the entire apical meristem at a magnification of 210 diameters was made for each stem tip. Usually about 25 sections were required to make a complete series through a meristem. Very little shrinkage was observable in any of the tissues.

Since comparative volume measurements of the apical meristem were one of the important objects of this study, it was essential to define the term for the purposes of the investigation and to be able to recognize as the meristem a region the extent of which could be clearly defined in the material. For the following discussion the term "meristem" may be defined as that area at the tip of the stem in which the cells are isodiametric and non-vacuolate, or in which the vacuoles are extremely small. The region <sup>1</sup> Received for publication April 24, 1939.

selected presumably represents that area in which, at division, at least one of the daughter cells always remains undifferentiated. It is thus the truly embryonic portion of the meristem and the region of most active division. There is some tissue outside this area in which cell division occurs, but in such cases differentiation has already begun. Observation of large numbers of sections leaves no question that the region selected does represent that of most active division and that its boundaries can be sharply delimited. The number of mitotic figures present, the more intense staining reaction, and the complete absence of any differentiated cells unite in distinguishing this region from the rest of the growing point. Meristems of the plants in cross I [Lycopersicon esculentum  $\times$  L. pimpinellifolium (Whaley, 1939)] are illustrated in figures 5-15.

Meristem volume was measured in the following manner: plates of uniform thickness of 1.3 mm. were made from a specially prepared modelling wax in a wax-plate machine which could produce them accurately to tenths of a millimeter in thickness. The thickness of the plates (1.3 mm.) was determined by multiplying the thickness of the original tissue sections by the magnification, taking the result to the nearest tenth of a millimeter. The projected drawings made from serial meristem sections were placed upon the wax plates, and by means of a steel needle cutting through both paper and wax, wax patterns exactly the size and shape of the drawings were secured. The wax sections made from each of the series of projection drawings for each individual stem tip were then weighed together. Knowing the specific gravity of the wax, it was possible to determine the volume of the plates making up each series. By dividing this volume by the magnification used, the actual volume of the meristem could be calculated. Although a certain amount of error may be introduced by this method, it seems to be the most satisfactory one possible. The results obtained are consistent and reliable enough for comparative purposes.

From the series of sections through each meristem, the median section, or what appeared nearest to a median one, was chosen for the measurement of cells and nuclei. From this section camera lucida drawings were made of cell and nuclear outlines, using a magnification of 1,850 diameters. Where there were

many cells, at least seventy were drawn, but where the cell number in a median section was small, as many as possible were drawn, in no case less than thirty-five. The cells in the apical meristem are irregular polyhedrons in shape but tend to be approximately isodiametric in outline. Volume was calculated by measuring the longest and the shortest diameter of each projected cell outline, determining the average, dividing by the magnification, and cubing the resulting value. This method, of course, gives the volume of the cell on the basis of a cube, and hence all volumes are probably somewhat too high as absolute measurements. The actual volume of polyhedral cells must lie between that of a cube and that of a sphere of equal diameter. The measurement of cells, and particularly of such small irregu-

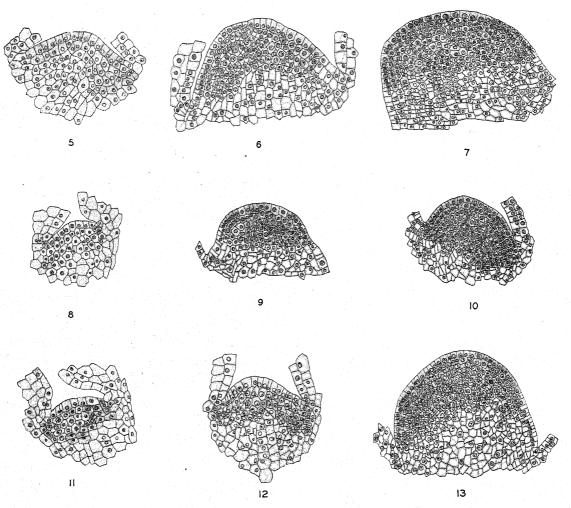

Fig. 5-13.—Fig. 5, 6, 7. Parent A. Camera lucida drawings of median longitudinal sections through the apical meristem in the seed, after 7 days' growth and after 77 days' growth, respectively, showing developmental changes in the size and shape of the meristem and in the size of its cells and nuclei.  $\times 133$ .—Fig. 8, 9, 10. Parent B. Same as preceding figure.—Fig. 11, 12, 13. Hybrid A  $\times$  B. Same as preceding figure.

lar cells as occur in the apical meristem, is extremely difficult. The results are, therefore, of doubtful validity as absolute measurements; but when large numbers are used, the results are satisfactory for comparative purposes. Nuclei were measured by the same technique used for the cells. As meristem nuclei are spherical, their volume was calculated by substituting diameter measurements in the formula for the volume of a sphere.

Cell number was obtained in each case by dividing the volume of the meristem as a whole by the volume of the cells. The results permit a comparison of relative cell numbers in any series at any time. They should not be taken, however, as absolute counts of cell number, partly because of the inadequacy of the cell size measurements, as shown above, and partly because to obtain accurate actual counts it would be necessary to take into account the difference between the dermatogen cells and the remainder of the meristem. The former tend to remain con-

stant in size during development. In no case were any of these included in the cells measured to determine cell volumes.

MERISTEM VOLUMES.—The meristem volume measurements are given in table 1. The entry at zero days is the volume of the plumular meristem in the seed embryo. In each cross the volume of the plumular meristem of the hybrid is intermediate between those of the parents. This intermediate position is maintained throughout the greater part of development. The changes in volume during the period in which the seedlings were grown on damp paper (the entries at 2, 4, and 6 days) are probably not significant because of the absence of any food supply other than that stored in the seed. There is, however, a marked change in meristem volume during the course of later development. As growth takes place, the volume of the apical meristem increases, reaching a maximum late in the grand period of growth and then falling off sharply to a relatively constant size. The point at which the decrease in volume takes place corresponds in most types with the falling off of the growth rate (Whaley, 1939).

The rather large variation within each group in the values obtained is no doubt due largely to the amount of error introduced by the involved method used. It is possible, however, that some of it may be due to differences in the point in the plastochron at which the samples were taken. That is, there may be a considerable difference in the volume of any given meristem just before and just after production of a leaf primordium, and no attempt was made to determine the length of a plastochron or to synchronize the intervals between samplings to this length.

Cross I (Lycopersicon esculentum  $\times$  L. pimpinellifolium).—The differences in the developmental behavior of the meristem of the parents and the hybrid of this cross suggest a relation of meristem volume changes to heterosis. A notable variance between the hybrid and its parents is that the decrease following the attainment of a maximum meristem volume comes later in the hybrid than in either parent. It occurs about two weeks later than in parent A and a week later than in parent B, which it resembles most in growth. This change corresponds closely to the points at which growth begins to slow down in all three types. There might, therefore, appear to be a correlation between the length of time during which the meristem remains large and the duration of growth, and thus the appearance of heterosis.

Cross II (Lycopersicon esculentum var. "Chinaman" × L. racemigerum).—The behavior of meristem volume here differs in two ways from that in cross I, although here, too, the hybrid is intermediate between its parents as to plumular meristem size. First, the apical meristem is larger throughout development in both C and D and their hybrid

tween the development behavior of meristem volume and the appearance of hybrid vigor.

Cell volume.—An estimation of meristem cell size and its changes during development was undertaken in an attempt to ascertain whether heterosis might be manifest in some process reflected in cell size relations rather than in meristem size. The results are given in table 2 and figures 1 and 2. The most important fact to be observed is that in all cases, as development proceeds, cell size decreases. Actually no given cell decreases in size, but the apparent decrease results from a progressive reduction in the amount of cell growth between successive divisions. This diminution of cell size proceeds until about the time the growth curve begins to flatten off. At this point a minimum level is reached and maintained.

Cross I.—In this cross the plumular meristem cell size of the hybrid is intermediate between those of its parents. Nevertheless, there are two marked developmental differences between the hybrid and the pure types. Diminution of the cell size takes place less rapidly in the hybrid. Figure 1 shows this fact clearly, for the slope of the hybrid curve is much less steep than those of the parents. As a result, throughout early development the cells of the hybrid meristem are larger than those of its parents. A second difference lies in the fact that the minimal size, which is reached at maturity in each type, is smaller in the hybrid than in its parents.

Cross II.—This cross presents the same picture as the previous one, except for two facts. First, the plumular meristem cell size of the hybrid is smaller than that of either parent. Here again size decreases much more slowly in the hybrid, so that, despite its initially smaller cells, the hybrid cells are larger throughout most of development. Second, as compared with cross I, meristem cell size in all types here decreases much more rapidly (figure 2). This difference is correlated with a difference in general growth rates (Whaley, 1939, fig. 1, 2, 3 and 4, 5, 6). There does not appear to be much difference between the final minimal level reached by the hybrid and the pure types in this instance (table 2). Perhaps for this reason the increase of the hybrid over its parents during the final stages of growth is much less noticeable here than in cross I.

In both crosses there is a relation between the rate of change in meristem cell size during development and the degree of heterosis shown, diminution of cell size proceeding much less rapidly in the hybrids than in the pure types.

Nuclear volume.—Nuclear volume of meristem cells in parents and hybrids was also compared (table 2, fig. 3, 4). In both crosses the nucleus of the hybrid is intermediate in size between those of the pure types in the seed. In the initial stages of growth the nucleus behaves differently from the cell in that its volume increases for a short time either during or immediately after germination. The apparent absence of any increase in type C may be due to an error of measurement, or the increase may be followed by a decrease of equal magnitude during the

first seven days. At any rate, after seven days five of the six types have nuclei larger than those in their respective seed embryos, and the hybrid is in each instance markedly larger in this respect than either parent. Following this initial increase, the nucleus decreases in size during development in much the same manner as does the cell. Relatively, however, it decreases at a much less rapid pace. In both crosses a minimum nuclear size is reached at the same time that the cells reach their minimum size. As with the cells, this final size is lower in each of the hybrids than in the pure types.

Cell number.—As seen in table 1, the hybrid does not have a larger number of meristem cells than the parents in either cross, except, as pointed out above, in the final stages of growth. The behavior of cell number during development is, of course, a function of the relation between meristem volume and cell volume. Generally, cell number increases during development, with a slight decrease attending the change in both cell and meristem volumes at the attainment of maturity.

Discussion.—Size in an organism depends upon three variables: first, the size of the original cell or group of cells from which the organism grows; second, the rate of growth; and third, the duration of growth. The most obvious aspect of hybrid vigor is the attainment of greater size by the hybrid than by its parents. The first step toward an understanding of heterosis must be to determine which of the variables are concerned in the ultimate differences observable between the hybrids and the pure races. The results in the present investigation make it possible to evaluate the part played by each of these factors in the development of hybrid vigor in Lycopersicon. Since this paper is concerned mainly with post-embryonic growth, embryo size in the seed will be considered first. It is realized that any embryo size differences are in turn due to differences in rate or duration of growth between fertilization and the maturation of the seed.

Ashby (1930, 1932) postulated that the size of the embryo is the most important of the factors in relation to heterosis, and Luckwill (1937) found evidence to support him. The results presented here do not agree with those of Ashby and Luckwill. In cross I the hybrid embryo is larger than those of the parents, but in cross II, with almost as much heterosis, the hybrid embryo is intermediate in size between those of its parents. East (1936) pointed out that there are many other cases in which the embryos of vigorous hybrids are smaller than those of their parents.

There remains, however, the possibility, suggested by both Ashby and Luckwill, that the size of the actual meristematic tissue mass (the "meristematic capital"), and not the whole seed embryo, may be the important factor. If the actual mass of meristematic cells in the embryo is the determining factor in heterosis, then the measurement of the meristems at the tip of the stem or the root should indicate a volume difference in favor of the hybrid. The meristem of the shoot rather than that of the root was

chosen for measurement because from it originate the parts of the plant with which heterosis is known to be concerned, and because its developmental history may be more readily observed. Luckwill (1937) made some observations of shoot primordia in a hybrid tomato and its parental types, from which he concluded that the hybrid meristems were larger than those of the pure types. Luckwill's drawings, however, include differentiated tissue which must be many times as large as the primordia of which he speaks, and are without much value as a measure of the active meristematic region. Ashby and Luckwill were concerned with the size of the plumular meristem when they assumed the amount of "original meristematic capital" to be the immediate controlling factor in the development of hybrid vigor. Reference to table I shows clearly that there is no relation between the size of the plumular meristem and the presence of heterosis, since in both crosses the hybrid is intermediate between its parents.

There is still the further possibility that meristem size at some time during later development may be a deciding factor. At first glance the results from cross I might seem to lend support to such an idea, since, although during the greater part of development the hybrid meristem maintains its intermediate position, it retains its large size considerably longer than either of the pure types. The results from cross II make the acceptance of this idea impossible, for if there is actually a decrease in meristem size here (and in D and C X D this is not at all certain), the hybrid decreases earlier than the parental types. It is, therefore, clear that meristem volume, at least in so far as the conception of the meristem here presented is concerned, either in the seed embryo or during development, is not concerned in heterosis.

Size of the meristem seems to be correlated directly with size of the lateral determinate organs of the plant, as suggested by Sinnott (1921), rather than with total plant size. Evidence for this assumption is seen in the sizes of the meristems in each cross and also in the differences between the meristems of the plants in cross I and cross II. The cross II plants are all larger as to organ size than those of cross I and have correspondingly larger meristems. Sinnott has shown that for a time during development there is progressive increase in the size of the organs produced. If size of an organ is determined by size of the meristem from which it comes, then an increase in organ size during development should be paralleled by an increase in meristem size. The material here studied shows that this is the case.2 The problem of the inheritance of organ size in plants thus becomes one of the inheritance of meristem size.

The close relation between the size of the meristem and of the determinate organs which it produces, and the absence of a relation between heterosis and meristem size, explains the fact so often

<sup>2</sup> The decrease in meristem volume which sometimes accompanies the attainment of maturity may be the result of a greatly diminished rate of cell division or of a diversion of nutrient substances to the developing fruits. It is usually paralleled by a decrease in organ size.

observed that heterosis does not express itself in the size of these determinate organs.

Meristem volume is also related to the growth habit of the plants. The gene d, which results in the dwarf habit when present in the homozygous condition, seems to operate by increasing the size of the meristem. Large meristems produce thicker stems with less growth in length than those formed from smaller meristems. In both crosses the Dd hybrids have a tall growth habit, but in each case, because of heterosis, they are both taller and heavier than the tall parents. This size increase, which is due to greater growth and a larger number of plant parts, is not accompanied by an increase in meristem size. The dwarf parent in each instance has the largest meristem. Meristem volume is thus related to gene D-d and not to the presence of heterosis.

The second factor is the rate of growth. Ashby (1930, 1932, 1937) has presented evidence to prove that at least during the period of exponential growth there is no difference in rate of weight increase between the hybrid and the faster-growing of its two parents. The author's results are in agreement with Ashby's in so far as there does not appear to be any significant difference during this period. In the very early seedling period, however, the hybrids grow much faster than the pure types. Failing to find any difference in the rates of exponential growth, Ashby supposed the advantage which the hybrids possessed to be the result of greater embryo size—an assumption in which he apparently was not justified, at least in so far as tomatoes are concerned. The size advantage of the hybrid may be the result of more growth in the very early seedling stages. Sprague (1936) has also found such to be the case in maize. If, in addition, the hybrid embryo is larger than those of the parents, as in cross I, a still greater hybrid superiority may result.

The third factor, duration of growth, does not seem to be primarily concerned in the development of hybrid vigor. Ashby has shown that in both maize and tomatoes the hybrid does not exceed its faster-growing parent as to length of the period of exponential growth. The data presented here support this conclusion, but indicate that while growth may begin to slacken in the hybrid at the same time that it does in the parents, it usually falls off less rapidly in the hybrid, with the result that there is more growth during later stages. These later differences are accentuated if the whole plant rather than the vegetative parts alone are considered.

Hybrid vigor in the *Lycopersicon* crosses reported here is thus the result of more rapid growth of the hybrid during the early stages, augmented in the final stages by less rapid slackening of growth. It seems probable, therefore, that the operation of heterosis depends upon more rapid growth at some time in development. It may take place during the development of the embryo, in the early seedling stages, in the final fruiting stages, or in any combination of these. It seems to be absent or restricted during the grand period of growth.

Although volume of the meristem does not seem to be in any way concerned in hybrid vigor, a study of developmental changes in the meristem does furnish some very important clues as to the manifestation of heterosis. The first of these lies in the behavior of cell size.3 Whereas differences in cell size at the meristem at any given time are not one of the manifestations of heterosis, the behavior of cell size during development is evidently closely related to the duration of growth and thus to final size differences. Developmental changes in the size of apical meristem cells have been briefly reported in grass embryos by Rössler (1928) and in soybeans by Murneek and Gomez (1936). These results, and the much more extensive ones here presented, indicate that there is a progressive diminution in cell size in the apical meristem of an annual plant from germination until the end of the grand period of growth. At about this point, which marks the end of active growth and the onset of maturity, a minimal cell size is attained which thereafter remains essentially constant. This fact is of rather general significance for an understanding of growth, and a comparison of pure races and hybrids in this regard is, therefore, important in an analysis of heterosis. The diminution in cell size during development evidently results from failure of the daughter cells to equal the size of the mother cell before they divide again. The balance between the rate of division and rate of enlargement determines the relative rate of cell size change. It is evident from a comparison of the slopes of the curves (fig. 1, 2) that during the early stages of growth the decrease in cell size until uniform minimum size is attained takes place less rapidly in the hybrids than in either of the pure types. There are two possible reasons; cell division may be less rapid, or rate of intake of materials, and thus of protoplasmic synthesis, may be more rapid. The first possibility is unlikely, because the hybrid does not grow more slowly than either parent. Thus the difference between hybrids and pure types seems fundamentally to be one of metabolism. In both, cell size at the meristem is gradually falling as maturity approaches, each generation of daughter cells failing to reach the size of their mother cells; but in the hybrids the more vigorous production of new synthetic material markedly retards this process, deferring the attainment of minimal cell size and resulting in more growth, and thus in the result which we recognize as heterosis.

Nuclear volume seems also to be of significance in the distinction between hybrid and pure types. Bindloss (1938) studied nuclear size in the plumular meristems of inbred and hybrid maize. In one cross the plumular meristem nuclei of the hybrid were intermediate in size when compared with those of the parents, while in another the hybrid nuclei were

<sup>3</sup> Kostoff and Arutiunova (1936), Malinowski (1935), and others have presented evidence to show that mature cell size is not a factor in heterosis. In the present experiment neither hybrid possessed significantly larger cells than the parents when petiole parenchyma cells were used as an index. Accordingly, no further attention has been given to cell size, other than in the meristem.

larger. In both Lycopersicon crosses reported here the hybrid has plumular meristem nuclei intermediate in size between those of the parental types. Here, too, as with the cells, absolute size in the plumular meristem offers no suggestion of any relation to heterosis. The key to the situation lies in the developmental behavior of the nuclei. Early growth is accompanied by a great increase in nuclear size. The greater increase in the hybrids than in the pure types gives them a nuclear size advantage which is then maintained throughout most of development. The hybrids differ from their parents further in that the minimal size to which their nuclei finally decrease is much smaller than that for the pure races. For some reason the hybrid nuclei possess the ability to divide at a smaller size than those of the parental types. These nuclear differences, like those of the cells, seem to be indicative of some physiological difference between the hybrid and the pure types.

Changes in cell and nuclear size during development make it desirable to calculate the cell/nucleus ratio in order to determine whether the absolute size of the cells and nuclei or the relationship of one to the other is important. Sinnott and Trombetta (1936) and Trombetta (1939) have shown a definite relationship to exist between rate of increase in size of cell and nucleus. They found nuclear volume to increase generally about two-thirds as fast as cell volume. As a result, the ratio of cell size to nuclear size is much greater in larger cells than in smaller ones. This same relation obtains in the material studied here (table 2, fig. 5-15), although the course of development is from larger to smaller cells rather than vice versa. Sinnott (1939) has shown that in simple determinate growth, as in the development of fruits, size of the cells increases until finally a point is reached at which cell division ceases. In the indeterminate growth of the meristem the reverse takes place, for here the cells become progressively smaller until finally they reach a minimal size. Cessation of cell division and thus of meristematic activity may be in part the result of changes in the relation of cell to nucleus.

We may conclude, therefore, that the direct causes of heterosis lie primarily in physiological differences between hybrids and pure types. The presence of these differences is apparent in the more rapid growth of the hybrids at some time during development. This more rapid growth need not be confined, as Ashby and Luckwill believe, to the period of development of the embryo. These metabolic differences may also be demonstrated by a comparative study of the meristems of hybrids and their parents, for the synthesis of protoplasm, as indicated by size changes in meristem cells and nuclei, is more rapid in the hybrids. A knowledge of conditions at the meristem, therefore, contributes markedly to an understanding of heterosis, although meristem volume does not seem to be directly concerned.

#### SUMMARY

A study was made of certain developmental changes in the volume, cell size, and nuclear size in

the apical meristems of two Lycopersicon species crosses showing heterosis.

No relation was found, either in the embryo or during development, between the volume of the apical meristem and heterosis.

Size of the meristem is related to the size of the determinate organs developed from it. These organs are unaffected by heterosis.

Cell and nuclear size in the meristem was found to

decrease during development, but much less rapidly in the hybrids than in the pure types. The attainment of a minimal cell and nuclear size is associated with the onset of maturity. These differences seem to be due to a fundamental metabolic difference between pure types and hybrids.

# A REVISION OF THE SUBGENUS DIHOLCOS OF THE GENUS ASTRAGALUS <sup>1</sup>

### C. L. Porter

Because of the increasing interest in the seleniferous plants, many of which are Astragali, and the attendant need for a critical examination of the many species of that group, an intensive study of the genus Astragalus in its broad sense has been started. This paper deals with only one of the subgenera of the genus. Other subgenera will be similarly treated as the work on them is completed.

The first question naturally arising is that of whether to treat the group as a genus containing several well-defined subgenera, or to maintain these major divisions of the group as distinct genera. There are good reasons for either treatment, but the former method is here regarded as more desirable for the following reasons: (1) Although there are undoubtedly good generic differences in the group, these are mostly based on fruit characters alone and are not evident in immature specimens. (2) Those divisions of the group which are distinguishable on

<sup>1</sup> Received for publication May 29, 1939. Contributions from the Department of Botany and the Rocky Mountain Herbarium of the University of Wyoming, No. 174. vegetative characters (such as the spiny leaves in the subgenus Kentrophyta and the trifoliate leaves in the subgenus Orophaca) are certainly as closely related to other members of the group as are those which differ chiefly in fruit characters. (3) Field workers find it desirable to be able to give a generic name to a plant even though it lacks the maturity necessary for a generic diagnosis which is based on fruit characters. (4) Herbarium workers find it desirable to be able to place a specimen in a genus at least, even though it may be immature, and thus file it in the cases with its near relatives. If the genus is not known, it must be placed in the enquirendi for the whole family. Furthermore, the segregates from such a group, when treated as genera, would be filed in an herbarium alphabetically, and thus groups which are more closely related to each other than to other groups in the family might be widely separated in an herbarium merely because they have been designated by generic names which start with various letters of the alphabet.

In the course of this study the writer has seen either type or topotype material of all species and

synonyms with the single exception of that of Astragalus bisulcatus, a very well-known species whose type is not available in this country. In addition, many of the specimens annotated by Dr. Rydberg and by Mr. Marcus Jones have been studied. The valuable collection of Mr. George E. Osterhout, a close friend of Mr. Jones, which contains most of the plants distributed by him, has been studied, together with that of the Rocky Mountain Herbarium. The writer has also studied and named many sheets of specimens from the Soil Conservation Service through the assistance of Mr. L. N. Goodding, botanist for that branch with headquarters in Albuquerque, New Mexico. Many specimens have been studied from the collection of Prof. O. A. Beath, Research Chemist at the University of Wyoming, who has collected extensively wherever Astragali are likely to be seleniferous. The writer also has seen most of the species growing in the field in Wyoming, Utah, Colorado, and New Mexico, and has collected numerous specimens of the species encountered. Because of the excellent representation of specimens seen as indicated above, it was not deemed essential that the collections of all the large herbaria be stud-

ied, except as to the borrowing of types.

The writer is indebted to the following for assistance in the preparation of this treatment: the herbarium of Pomona College, California, for the loan of the type of Astragalus oocalycis; the herbarium of the New York Botanical Garden for the loan of the type of Astragalus haydenioides (Diholcos micranthus); Prof. O. A. Beath and Mr. Carl Gilbert, research chemists at the University of Wyoming, for helpful data on distribution and variation

of several species; Mr. L. N. Goodding, botanist for the Soil Conservation Service, for specimens collected particularly in the southwest; and to Dr. Aven Nelson, curator of the Rocky Mountain Herbarium, for helpful advice and suggestions.

ASTRAGALUS SUBGENUS DIHOLCOS RYDB.—Plants perennial, often caespitose, 2-10 dm. high, with erect or sometimes decumbent stems from woody roots. Leaves pinnately compound, with about 10 (8-15) pairs of linearoblong to elliptic leaflets and free stipules. Flowers in dense or loose racemes or spikes, white, cream-colored, or purple, horizontally spreading to reflexed at maturity, 7-15 mm. long. Calyx campanulate or urceolate, gibbous at the base above, with narrowly lanceolate to subulate teeth. Corolla with oblanceolate to narrowly obovate, retuse, clawless banner; the wings with an acute basal auricle, their blades about equaling the banner, obliquely oblanceolate; the blades of the keel broader and broadly lunate. Pods stipitate, coriaceous, the body 8-20 mm. long. oblong, straight, 1-celled, with no intrusion of either suture, 2-grooved ventrally and convex dorsally, glabrous or strigose and smooth or cross-reticulate.

Type species: Astragalus bisulcatus A. Gray.

### Key to the species

Calyx campanulate, not inflated, strigose, leaflets ovate

Body of pod 11 mm. long or more.....1. A. bisulcatus Body of pod 10 mm. long or less

linear......4. A. oocalycis

Since the above tabulation provides a fairly accurate description of the species, the discussion to follow will be limited to matters of variability and

Astragalus subgenus Diholcos	bisulcatus	Haydenianus	hay denioides	oocalycis
Pods glabrous or strigose	gors	s	s	g (when young)
Length of body of pod (mm.)	12-20	8-10	8-9	a
Length of stipe of pod (mm.)	3-4	3-5	3-4	a
Pod cross-reticulate	No	Yes	No	Yes
Color of flowers	Purple, rarely white	White, with pur- ple-tipped keel	Cream	White or cream, with purple- tipped keel
Length of corolla (mm.)	1220	8-12	6-7	15-16
Calyx tube inflated in age	No	No	No	Yes
Length of calvx tube (mm.)	4-6	3	2-2.5	8
Length of calyx teeth (mm.)	2-6	1-2	1-1.5	2-3
Pubescence on calyx	Strigose	Strigose	Strigose	Shaggy-villous
Shape of leaflets	Oblong to oval	Oblong to oval	Linear or lance- oblong	Linear or oblong
Length over width of leaflets (mm.)	10-25	7-25	7-20	10-40
	4-10	3-5	2-4	1-3
Number of leaflets	15-27	15-23	17-25	15-19
Range	Manitoba and Alberta to Ne- braska, Okla- homa, Idaho, Colorado, Wyoming, and northern New	Utah, Wyoming, Nevada, Colo- rado, and New Mexico	Colorado	Southern Colo- rado and northern New Mexico

<sup>&</sup>lt;sup>a</sup> Mature fruit unknown.

synonymy, together with the citation of a few representative specimens that have been distributed to various herbaria.

1. ASTRAGALUS BISULCATUS (Hook.) Gray, Pacific R. R. Rep. 12: 42, 1860. Phaca bisulcata Hook., Fl. Bor. Am. 1: 145, 1831. Tragacantha bisulcata Kuntze, Rev. Gen. 943, 1891. Astragalus bisulcatus f. hedysariformis Gand., Bull. Soc. Fr. 48: XIV, 1902. Astragalus Haydenianus f. leiocarpa Gand., l. c. 48: XV, 1902. Astragalus bisulcatus f. decalvans Gand., l. c. 48: XV, 1902. Diholcos decalvans Rydb., Bull. Torr. Bot. Club 32: 664, 1906.

The campanulate or tubular calyx tube combined with the large flowers and fruit distinguishes this species from the others. The color of the flowers is usually a deep purple, but it may vary from that through pale lavenders to cream-colored or white. Furthermore, the pods are usually strigose, but the degree of this character may vary, and sometimes the pods are quite glabrous. The color of the corolla is not correlated with the strigosity or glabrousness of the pods, therefore there appears to be no basis for the recognition of Gandoger's forma decalvans in any category.

Type—collected by Drummond, from the plains of the Saskatchewan, Canada, in the Kew Herbarium.

2. ASTRAGALUS HAYDENIANUS A. Gray, in Bull. U. S. Geol. and Geogr. Surv. Terr. 2: 235, 1876.

Tragacantha Haydeniana Kuntze, Rev. Gen. 945, 1891. Astragalus Haydenianus var. major Jones, Zoe 2: 241, 1891. Astragalus Haydenianus var. nevadensis Jones, Zoe 2: 241, 1891. Astragalus grallator S. Watts., Zoe 3: 52, 1892. Astragalus demissus Greene, Erythrea 1: 221, 1893, not A. demissus Boiss. and Heldr., 1849. Astragalus Jepsoni Sheld., Minn. Bot. Stud. 1: 22, 1894. Astragalus scobinatulus Sheld., l. c. 1: 24, 1894. Astragalus Haydenianus f. Nelsonii Gand., Bull. Soc. Bot. Fr. 48: XV, 1902. Homalobus grallator Rydb., Bull. Torr. Bot. Club 32: 666, 1905. Diholcos Haydenianus Rydb., Bull. Torr. Bot. Club 32: 664, 1905. Diholcos scobinatulus Rvdb. l. c. 40: 51, 1913. Diholcos Jepsoni Rvdb., N. Am. Fl. 24: V, 281, 1929. (The synonym sometimes given: Astragalus bisulcatus var. Haydenianus Jones, Zoe 2: 240, 1891, was never published by Jones. In the reference given he merely stated that when the species Haydenianus is reduced, it will become a variety of A. bisulcatus. At the time Jones believed the reduction of Haydenianus to a variety was justified, but he apparently changed his mind later as this was never done by him.)

This species is distinguishable by the combined characters of small flowers and small, conspicuously cross-reticulate pods. The shape of the pods, whether acute or blunt, the length of the stipe, and the thickness of the leaflets are variable characters and do not justify specific or varietal distinctions.

Type—collected by H. N. Patterson, on Grand River, Middle Park, in the U. S. National Herbarium.

3. ASTRAGALUS HAYDENIOIDES n. nov. Diholcos micranthus Rydb., Bull. Torr. Bot. Club 34: 420, 1907. Not Astragalus micranthus Nutt., Jour. Acad. Phila. 2: 122, 1821. Not Astragalus micranthus Desv., 1814.

The citation for *Diholcos micranthus* Rydb. is given by Rydberg in the North American Flora as his Flora of the Rocky Mountains. This is an error.

The preoccupation of the combination Astragalus micranthus necessitates a new name for this species and the above name was chosen because of the striking resemblance of this species to A. Haydenianus from which it differs chiefly in lacking the cross-reticulations on the pod possessed by that species.

TYPE—collected by C. L. Shear, No. 3569, at La Veta, Colorado, in the herbarium of the New York Botanical Garden.

4. ASTRAGALUS OOCALYCIS Jones, Contr. West. Bot. 8: 10, 1898. Cnemidophacos urceolatus Rydb., Fl. Rocky Mts. 502, 1917. Astragalus urceolatus Green, MS, Rydb. Fl. Rocky Mts. 503, as synonym, 1917. Diholcos oocalycis Rydb., N. Am. Flora 24: V, 282, 1929.

The urceolate, shaggy-villous calyx tube which is inflated in age renders this species very distinct from all others of the group. Unfortunately mature fruits have apparently never been collected, the best obtainable being two very immature pods on the type sheet which were photographed and are reproduced herewith. This spring the writer visited the type locality to attempt to collect more mature specimens, but not a single plant of the species could be found in the bottom lands at Aztec, New Mexico, the location described by Wooton. Much of that area has been cultivated since his time and perhaps the plants have been exterminated locally. Other localities in the region likewise failed to produce a specimen.

The vegetative aspect of the species, as pointed out by Jones in his Revision of North American Astragali, resembles that of A. racemosus. The writer does not agree with Jones, however, that this species is possibly a freak. On the contrary, it is one of the most excellent and consistently distinct species in the entire genus.

Type—collected by Wooton, in bottom lands, Aztec, New Mexico, in the Pomona College Herba-

# EFFECT OF PHOTOPERIOD AND TEMPERATURE UPON THE GROWTH OF SEEDLINGS AND CUTTINGS 1

B. Esther Struckmeyer and R. H. Roberts

SEEDLINGS AND clons of several species that were grown in different environments for anatomical investigations2 made several interesting responses. Two of these were: (1) a conspicuous difference in the degree of variability of growth within a population for the different species of plants in the various environmental locations, and (2) the unlike reaction of seedlings and cuttings to photoperiod.

Material for a comparison of the response of the seedlings and clons to photoperiod was obtained by collecting seed from a single plant and then using this same plant as a source for cuttings. Several species of plants were grown, but emphasis will be limited to three: Centaurea cyanus L. (cornflower), Antirrhinum majus L. (snapdragon), and Petunia hybrida Vilm. When the seedlings and the plants from cuttings were two to three inches tall, the plants were placed in the different temperature locations with different lengths of day in each. Cool, medium, and warm houses with night temperatures of 55°, 65°, and 75°F., respectively, were maintained.

RESULTS AND DISCUSSION.—Because of the difference in the genetic composition of seedlings it is generally anticipated that a seedling population will show a greater amount of variability in growth than will a clon. The present results demonstrate that photoperiod and temperature also exert an influence upon the variability in growth of both clons and seedlings (fig. 1). This is shown by plants of a clon of Petunia that grew more uniformly in the short days at a cool temperature than in the long days at the same temperature. A similar effect of environment upon variability of growth was apparent with cuttings of alfalfa, Antirrhinum, Begonia semperflorens, Centaurea, Chrysanthemum, potato, Rudbeckia, and Salvia. The different species do not respond alike to a given environment, for one species may show a uniform growth, and another species may be variable under the same treatment. For example, Rudbeckia grew more uniformly in warm, long days, whereas Petunia plants were variable under this same treatment.

While seedlings show considerable variability in maturity and size of plants in some of the environments, they remain strikingly uniform in others. Seedling plants of Mathiola incana (stock) grew and flowered uniformly in cool long days, while they made a very variable growth in the medium temperature and short days (fig. 1B). A similar condition of

<sup>1</sup> Received for publication July 13, 1939.

uniformity and variability of growth, as influenced by environment, was noted for seedlings of Centaurea, Chinese cabbage, corn, Oenothera, peas, penny cress, pepper, Petunia, snapdragon, sorghum, and wild ground cherry.

It seems probable that the frequently reported "breaking up" of an apparently pure line of plants when grown for trial in an environment which is different from the one where the original selections were made is possibly the same type of phenomenon as shown in figure 1. This would indicate that the practice of growing new selections in different environments should probably be included in the technique of developing new strains of plants for breeding purposes.

It has already been pointed out that different varieties of a species show a wide range of adaptation

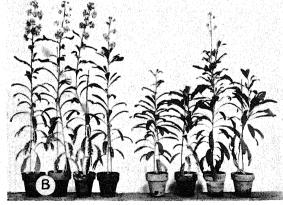

Fig. 1.-A. Petunia. Clons do not grow uniformly in all environments. The five plants at the left were grown in cool, long days. The five plants at the right were grown at a medium temperature with long days.—B. Stock. Seedlings show a relatively uniform growth in some environments. The plants at the left were grown at a cool temperature and long days. The plants at the right were grown at a medium temperature and short days.

695

to a particular environment (Roberts and Struckmeyer, 1938a, 1938b). From the present experiments it appears that the environment may at times play an important rôle in affecting the variability or uniformity of the growth of a population of plants.

A comparison was made of the flowering responses of cuttings and seedlings to photoperiod and temperature. Seedling plants of Petunia flowered in long days before they did in short days (fig. 2A). On the other hand, plants propagated by cuttings came to flower at practically the same time in both short and long days. Because these cuttings were taken from flowering plants, the question arose as to whether cuttings from non-flowering plants would respond in a similar manner. The next procedure was to make cuttings from both flowering and nonflowering plants. When these and seedlings of a comparable stage of growth were grown out-of-doors in the summer of 1938, cuttings from the flowering plants blossomed in both the long and short days; those from the non-flowering plants budded in both lengths of day after the same period of time; and seedlings budded in the long days but remained

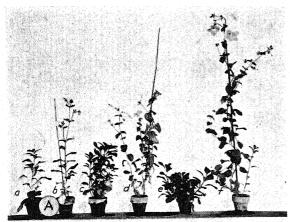

Fig. 2.—A. Petunia. Plants grown from seed. a, cool, short-day (budding); b, cool, long-day; c, medium temperature, short-day; d, medium temperature, long-day; e, warm, short-day; f, warm, long-day. Plants in short days remained vegetative except at a cool temperature, while all plants in the long days flowered.—B. Seedlings and cuttings. a, d, seedlings which remained vegetative in cool, short days and budded in cool, long days; b, e, cuttings from a non-flowering clon budded in both, cool, short and long days; c, f, cuttings from a flowering clon flowered at a cool temperature in both short and long days.

vegetative in the short days (fig. 2B). When this experiment was repeated in the fall and winter of 1938, similar differences in the responses of plants from different sources were noted.

Under the warmer night temperatures in the greenhouse during the summer, the different sets of plants gave similar flowering responses. The seedlings and both lots of cuttings were vegetative in short days and flowered in the long days (fig. 3).

Fig. 3. Seedlings and cuttings from a clon of Petunia. A, seedling; B, cutting from non-flowering clon; C, cutting from flowering clon; D, seedling; E, cutting from non-flowering clon; F, cutting from flowering clon. A, B, and C were in warm, short days, and D, E, and F were in warm, long days. The short-day plants were vegetative and the long-day plants flowered when kept warm.

A series of plants of snapdragon gave responses similar to those reported for *Petunia*. During the winter, cuttings from flowering plants flowered in all locations at about the same time, while seedlings flowered only in the long-days after a similar length of time. The plants grown out-of-doors in the summer responded differently to temperature. The seedlings remained vegetative for a considerable time, plants from non-flowering cuttings soon budded, and those from flowering cuttings quickly flowered.

Plants of *Centaurea* reacted like *Petunia* and snapdragon. Figure 4 shows the type of growth made by seedlings and cuttings of *Centaurea* in a cool location. Seedlings responded to photoperiod more strikingly than did cuttings. In a warmer location both seedlings and cuttings gave photoperiodic responses.

Since previous observations have shown consistent differences in the anatomy of flowering and nonflowering plants (Struckmeyer and Roberts, 1939; Wilton and Roberts, 1936; Wilton, 1938), samples of plants of Petunia were taken to determine whether the anatomical structure would throw any light upon the question of why the seedlings and the two lots of cuttings react differently to some combinations of photoperiod and temperature. Differences in the vascular anatomy of flowering and non-flowering stems as to the degree of cambial activity, the amount of phloem and xylem formation, and the cell sizes and maturity of the tissues have been repeatedly noted. As already reported for other regenerating shoots, the formation of new phloem as well as xylem below the regenerating node is associated with a vegetative shoot (Struckmeyer and Roberts, 1939). When the new shoot flowers rather quickly,

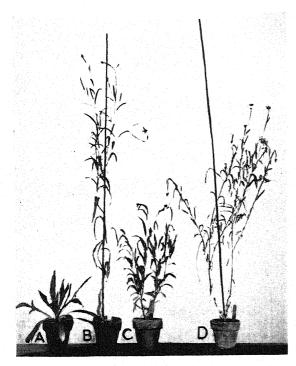

Fig. 4. Centaurea. A, seedling, short-day; B, seedling, long-day; C, cutting, short-day; D, cutting, long-day. The plants grown from seedlings remained vegetative in the short days and flowered in the long days. The cuttings on the other hand flowered in both lengths of day.

the ring of new tissue appears to be composed almost entirely of xylem cells.

An examination of sections of the original cuttings from non-flowering plants revealed the characteristic type of structure which is generally associated with the vegetative state, as shown by figure 6. The cuttings from flowering plants possess anatomical characteristics which are consistently found in flowering plants (fig. 8).

Figures 5 to 8 show cross-sections of stems of plants B and E, figure 3. In warm short days the cuttings from non-flowering plants remained vegetative. The original cutting still possessed an active cambial region with phloem and xylem cells in the process of differentiation (fig. 5). The new vegetative shoot from this cutting displayed an active cambium forming xylem and phloem cells (fig. 6). In warm long days the cuttings from non-flowering plants blossomed rather early. Observations of the cross-section of the stem of the original cutting shows that the cambial region is limited to only a few meristematic cells. Xylem but not phloem was formed as the stems increased in diameter. The cell walls of the tissues have become thickened. The pericycle fibers also have thicker walls in the flowering than in the vegetative stem. The new flowering shoot from this cutting presented anatomical features similar to those described for the original cutting from flowering plants (fig. 8).

Cuttings from flowering plants gave rise to vegetative shoots in a warm short-day environment (fig. 3). From observations of the cross-section of the original cutting it was found to have acquired vegetative characteristics as the cambial region had increased in width and activity, and new phloem and xylem tissues were being formed (fig. 9). The anatomical structure of the stems of the new shoots was like that described for the vegetative shoots of the non-flowering cuttings (see fig. 6). In the long days the cuttings from flowering plants gave rise to shoots that flowered. Both the old and new stems possessed anatomical characteristics of flowering stems (fig. 10 and like fig. 8).

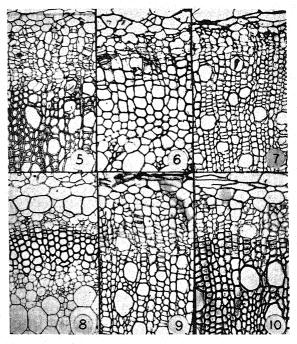

Fig. 5-10. Petunia.-Fig. 5. Cross-section of old nonflowering cutting which is producing vegetative shoots. This stem shows an active cambium and the differentiation of new xylem and phloem elements.-Fig. 6. Crosssection of new vegetative shoot which arose from the old cutting (fig. 5). The cambium is fairly active and the differentiation of new elements is in progress.-Fig. 7. Crosssection of old non-flowering cutting which gave rise to new shoots that flowered. The old cutting shows the cambium in a much less active condition than the vegetative cutting. The xylem and phloem cells have become mature, and few or no elements are in the process of differentiation.—Fig. 8. Cross-section of a new flowering shoot from cutting shown in figure 7. (Compare with figure 6.) The cambium is relatively inactive, and no new phloem cells are being formed.—Fig. 9. Cross-section of an old cutting which was taken from a flowering plant, but which gave rise to vegetative shoots in warm short days. The cutting has acquired the characteristics of vegetative stems. The cambium is active, and new vessels and phloem cells are being formed.-Fig. 10. Cross-section of cutting from a flowering plant which gave rise to flowering shoots in long days. (Compare with figure 9). The cambium is less active, and little vascular tissue is being formed.

When grown out-of-doors in the summer, the seed-lings and cuttings of *Petunia* did not give the same responses to photoperiod as the plants in the warm greenhouse (fig. 2B). Observations of sections of the cuttings from non-flowering plants and of the new shoots which were in an advanced stage of budding disclosed anatomical conditions like figures 7 and 8, which are typical of stems from flowering plants. The cuttings from flowering plants produced blossoms quickly in both long and short days. The anatomical structure of these stems and their new blossoming shoots was similar to those pictured for the plants in the warm long-day environment which remained in a flowering state (see figures 8 and 10).

In a warm environment photoperiod had a pronounced influence upon the growth of cuttings of Petunia. The anatomical structure and the type of growth of the cuttings from flowering plants was changed to the vegetative condition when grown in short days (fig. 3C). Seedlings and cuttings from non-flowering plants remained vegetative. Long days stimulated plants of all three sources to flower quickly (fig. 3D).

At a cooler temperature photoperiod had less effect, especially upon those plants grown in short

days.

The anatomical structure and type of growth of the cuttings from flowering plants continued unchanged, and plants from these cuttings blossomed earlier than plants from cuttings taken from nonflowering plants and also much earlier than seedlings.

The source of the plants—that is, whether they were seedlings or cuttings—determined to a large extent the kind and rate of response they made to

photoperiod.

#### SUMMARY

The degree of variability within a population of seedlings or of a clon was influenced by the environment. Both seedlings and clons were sometimes uniform and sometimes variable in growth, depending upon the environmental treatments to which they were exposed.

Cuttings of Antirrhinum, Centaurea, and Petunia responded differently to photoperiod and temperature than did the seedlings of these same genera.

The difference in response of cuttings from non-flowering plants and from flowering plants to environment was found to be associated with the differences in the anatomical structure of the original cuttings.

The flowering of seedlings was also found to be associated with the structure of the stem.

# NOTES ON THE DISTRIBUTION AND ECOLOGY OF ANANAS AND PSEUDANANAS IN SOUTH AMERICA <sup>1</sup>

Kenneth F. Baker and J. L. Collins

ALTHOUGH PINEAPPLE, Ananas comosus (L.) Merrill, and its near allies have been long considered native to South America, and opinions have been expressed<sup>2</sup> concerning more definite localization, it is only recently that comprehensive field and herbarium evidence have been available for such analysis. Such a study was impeded by the confused state of the taxonomy of the group, until this was clarified by Smith (1939).

<sup>1</sup> Received for publication July 14, 1939.

Published with the approval of the Director as Technical Paper No. 124 of the Pineapple Experiment Station,

University of Hawaii.

<sup>2</sup> Bertoni (1919) considered Paraguay as the country of origin of Ananas comosus. The view was expressed orally by a South American taxonomist who had specialized in the Bromeliaceae that Ananas and Pseudananas originated in the section of Paraguay, Argentina (Misiones), and Brazil (Paraná) called Guayra by the Guarani Indians.

The flora of South America is inadequately known, certain areas being unbotanized (Gleason, 1932), and this lack of information, evident for the Bromeliaceae as a family (Smith, 1934), is particularly conspicuous in the genera Ananas and Pseudananas. Perhaps because of technical difficulties in the collection and preservation of the fleshy flowers and fruits, these genera have been neglected entirely by many collectors, or specimens of the most fragmentary sort retained. All too many herbarium sheets consist of a single leaf and the general statement that the flowers were purple or lavender, thus giving no basis for evaluation.

This paper presents notes on the distribution and ecology of Ananas and Pseudananas with the hope of stimulating botanists to collect these plants in certain poorly known areas. These notes are based largely on field observations between October, 1938,

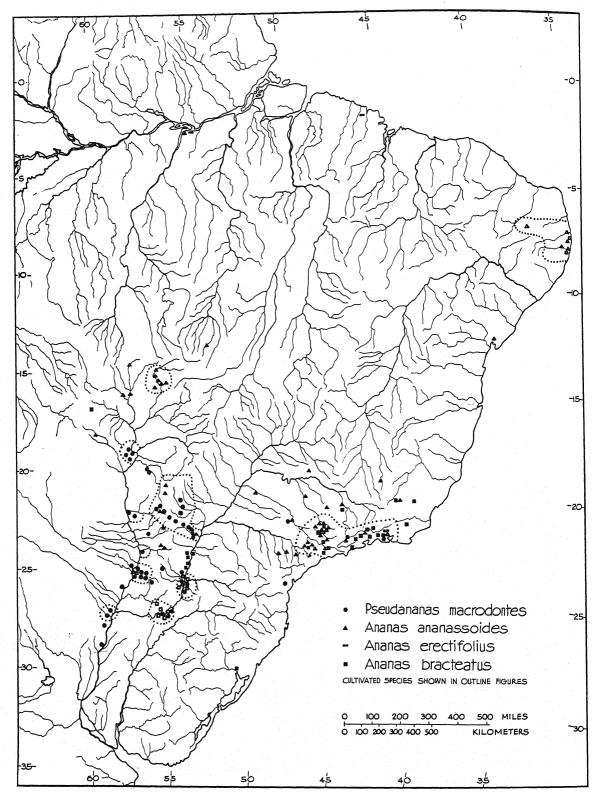

Fig. 1. Distribution of species of Ananas and Pseudananas in South America, based on field observations and on specimens in herbaria. Outline triangles in northeastern Brazil represent the ornamental A. ananassoides var. nanus. Outline squares on the Paraná River represent A. bracteatus var. typicus grown for fruit. Other outline figures indicate plants in botanical gardens and experiment stations. Areas within stippled lines were explored by the writers.

and March, 1939, during exploration for wild and cultivated forms of Ananas. Reliable data from specimens studied in the following herbaria have been incorporated: (1) Escola Superior de Agricultura e Veterinaria (Recife, Pernambuco, Brazil); (2) Field Museum of Natural History; (3) Gray Herbarium; (4) Instituto Biologico, Secção Botanico (São Paulo, Brazil); (5) Museu Argentino do Ciencias Naturales, Sección Botánico (Buenos Aires); (6) Museu de Historia Natural del Paraguay (Asuncion); (7) New York Botanical Garden; (8) United States National Arboretum (Department of Agriculture, Washington, D. C.); (9) United States National Herbarium. A few verified reports by competent observers have been included. While these data are not exhaustive, it is evident that extensive search among world herbaria would tend to increase reports from areas already covered rather than greatly to extend the distribution.

The nomenclature employed is that of Smith (1939), which was based in part upon the writers' herbarium material, photographs, and data. Dried specimens and photographs are filed in herbaria numbers 2, 3, 7, and 8 above as evidence of the species concepts followed. For brevity, the list of observed locations of the various species and of the verified recognizable herbarium materials is not presented, but is on file at the Pineapple Experiment Station, University of Hawaii, and at Gray Herba-

rium.

DISTRIBUTION.—The distribution of *Pseudananas macrodontes* (E. Morr.) Harms, *Ananas ananassoides* (Bak.) Smith, *A. bracteatus* (Lindl.) Schult., and *A. erectifolius* Smith is presented in figure 1. The varieties of the second and third species were not distinguished for this purpose. It will be noted that most of the locations fall between 14° and 29°S. latitude and between 59°W. and the east coast (39° to 50°W.).

The point of origin of three of the species probably lies within the area of 15° latitude and 9° to 20° longitude so delimited. More botanizing and field study will be required before the area can be more exactly located, but certain clues are afforded by this map. The proximity of P. macrodontes to A. ananassoides in southeastern Matto Grosso and to A. bracteatus in Misiones, Argentina, and southeastern Paraguay, and the contiguity of A. ananassoides and A. bracteatus in the Rio de Janeiro-São Paulo section suggest that all three species may be concomitant in the intervening territory.

P. macrodontes is centered largely in the drainages of the Paraná and Paraguay Rivers of Paraguay and adjacent Argentina and Brazil, but it extends eastward in a few places. Its spread to the west seems to have been limited by the salinity of the soil and streams and by the frequent droughts of the Chaco sections. The limiting condition in the east and northward along the coast is more obscure.

<sup>3</sup> Oral report by Teodoro Rojas and J. B. Jiménez, Museo de Historia Natural del Paraguay, Asuncion, who have botanized in the area.

In the interior the species is shut off on the north by the relatively dry, open Planalto of Matto Grosso and in the south by frosts, low temperature, and decreased rainfall.

A. ananassoides, the most generally widespread of the species, is apparently limited on the southwest by the decline of the Planalto on which it finds a favorable environment. An extension of this high zone southward into north central Paraguay accounts for the presence of A. ananassoides there. In certain areas along the margin of this plateau (e.g., the Campanario-Porto Felicidad section of Matto Grosso) A. ananassoides and P. macrodontes grow well and abundantly within a half mile of each other. Due to the abrupt transitions of rain forest and serrado<sup>4</sup> in southeastern Matto Grosso, this distribution is entirely compatible with the habitat of each.

From the known habitat of A. ananassoides, it seems probable that the species extends on the north until stopped by the Amazonian jungle. Information on the range in this direction and toward the northeast and southeast is very meager. A. ananassoides var. nanus was observed only as a cultivated ornamental in northeastern Brazil but was said to be wild in that region. If this be true, the range of the species is tremendously increased, but the point of convergence with P. macrodontes and A. bracteatus lies definitely further south.

A. bracteatus is known to occur in two distinct areas, one centering on the Alto Paraná and one in the Rio de Janeiro-São Paulo section of Brazil. In the former it occurs in proximity to P. macrodontes and in the latter to A. ananassoides. A. bracteatus probably will be found in the intervening territory, at present botanically almost unknown (Gleason,

1932).

A. bracteatus was almost always found in proximity to some habitation; on the Alto Paraná it occurred frequently in areas near former Jesuit missions. The obvious interpretation is that the plants have been spread and maintained by man. Antithetic to this, however, is the fact that the explored areas suitable for A. bracteatus are also favored agricultural regions and that the widespread practice of temporary utilization and abandonment of land (James, 1938) has decimated the species. The region between the Paraná River and the east coast has been less settled. It is, therefore, urgent that collections be made in the Brazilian states of Paraná and Santa Catharina before the present wave of colonization (Maack, 1938) has destroyed the native vegetation. One explanation for the present widespread survival of A. ananassoides is that it occurs on poor agricultural land; this tendency is commonly recognized and the plant utilized as an indicator of that condition by prospective purchasers. The lowland areas occupied by P. macrodontes also have been less intensively exploited.

<sup>4</sup> An ecological type characterized by tortuous trees (e.g., *Pithecolobium*) 10 to 15 feet high and brush in scattering open thickets; cacti are essentially absent and the sparse ground cover consists of grass and herbaceous plants. The soil generally is infertile and rainfall is low.

Fig. 2. Representative habitats of *Pseudananas* and three species of *Ananas* in South America. A (upper left). *Ananas comosus* wild or naturalized in open woods near Coxipo, Matto Grosso, Brazil. B (upper right). *Pseudananas macrodontes* under dense forest canopy at San Bernardino, Paraguay. C (lower left). *A. bracteatus* var. *typicus* growing at margin of clump of trees near Encarnacion, Paraguay. D (lower right). *A. ananassoides* var. *typicus* growing in the open brushy serrado near Mogy-Mirim, São Paulo, Brazil, showing inflorescences.

A. erectifolius is still too little known to warrant more than conjecture as to its distribution and affinities. It shows some similarities to the wild A. ananassoides and to the cultivated A. comosus which suggest that it may have evolved from those widely distributed species. More detailed information on the occurrence of these three forms in the southern

side of the Amazon drainage is needed to clarify this point.

A. comosus growing wild or semi-wild often has been reported from various parts of the tropics and sub-tropics. It should be noted that a great many of the important cultivated pineapple varieties will not survive such competition with other plants. This

species probably originated in or near the region discussed in this paper as the native home of the two genera. There is abundant evidence that the early peoples distributed the pineapple over a wide area, and Columbus is said to have introduced it into Europe from the West Indies. On this basis the occurrence of "wild" A. comosus may be dismissed as naturalized in many localities, as on the island of Hawaii and on Trinidad (Britton and Britton no. 2107) and probably also in British Guiana (Gleason no. 523) and Peru (MacBride no. 5482). Similar instances within or near the region regarded as the point of origin of the genus are more difficult to evaluate. The areas of A. comosus observed by the writers at Coxipo, Matto Grosso, and at Moura Brazil, Rio de Janeiro, are cases in point. The two distinct plants of these areas produced palatable fruit different from the naturalized pineapples observed at Prazeres and Tiuma, Pernambuco, and on the island of Trinidad. All of these sites were in or at the margin of semi-open stands of large trees, a shaded type of habitat similar to that of A. bracteatus. The plants were abundant, vigorous (fig. 2A), and occurred over large areas. It is uncertain whether these plants represent a link between the truly wild and the cultivated types, or merely strains of the latter retaining enough ancestral vigor to succeed untended. The widespread destruction of original ground cover, mentioned above, will make difficult the finding of intermediate forms.

The evidence presented above indicates that the key to more definite location of the point of origin of P. macrodontes, A. ananassoides, and A. bracteatus lies in the States of Paraná, Santa Catharina, and parts of São Paulo. The south side of the Amazon drainage is a second zone from which collections are needed for clarification of the distribution of

these genera.

Ecology.—The habitats of P. macrodontes, A. ananassoides, and A. bracteatus differ widely, a situation consistent with the variety of ecological conditions found in the probable area of origin designated above.

P. macrodontes is seen in interior lowland forests under canopies of variable density (fig. 2B). It occurs in plant associations ranging from the cactus-Erythrina-Prosopis type near Corrientes, Argentina, to dense rain forest near Campanario, Matto Grosso, Brazil. In the drier climate it was within a few yards to a half mile of the streams, dependent on the size of the body of water and the presence of a dense canopy and rather thick duff. Areas subject to overflow at high water were not occupied by P. macrodontes." whereas Bromelia and Aechmea were often observed in such locations. In areas of heavy rainfall the plants are not restricted to the streams or rivers and attain much larger size. The species, therefore, may be considered as adapted to humid lowland forests, but capable of withstanding considerable drought. In the Corrientes section, after three

<sup>5</sup> Bertoni (1919) reported a similar environment for this species.

phenomenally dry years, we observed numerous fertile fruits on stunted plants at a time when adjacent Opuntia was badly withered. Leaf mold was present almost everywhere this species was found; through this medium the plant sends stolons for distances up to six feet. This feature results in an open spacing within an area of P. macrodontes, as compared with the clumping evidenced by species of Ananas,7 and this spacing is distinctly advantageous in habitats

with reduced sunlight.

A. bracteatus is rather intermediate between Pseudananas and A. ananassoides in type of habitat. It does not grow in as profound shade as Pseudananas, being found on the fringes rather than extending far into a stand of trees8 (fig. 2C). There was some evidence of variability in capacity to withstand direct sunlight exhibited by representatives of this species from various sections of Brazil when growing at the Instituto Agronomico, Campinas, São Paulo. Although best development is attained in soil rich in leaf mold, the plant is often found in sites deficient in organic matter. The species tended to be restricted to depressions in which moisture obviously remained at a fairly high level; this condition was less noticeable in regions of abundant rainfall.

A. ananassoides represents the highest development of the genera in drought resistance. This plant is characteristically of the serrado of the Planalto. an area of tortuous stunted trees and brush in scattering open thickets (fig. 2D). Since the canopy over A. ananassoides is never dense, the plant is not handicapped by growth in large, dense mats. It also occurs in isolated clumps and occasionally was observed growing on termitaria in Matto Grosso. The latter habitat is an extreme example of the independence of the species in requirement of humus.

The habitat of A. erectifolius is conjectural, since the writers did not observe this species in the natural state. The fact that it is native in the Amazon area would suggest that it is a plant of the wet lowland. However, in gardens it made fairly vigorous growth in the drier region around Campinas, São Paulo.

The development of these species in such distinct natural habitats is an expression of their genetic differences. Unpublished records indicate that when

<sup>6</sup> The slender stolons bear chlorophyllous scales and progressively root at each node as the structure elongates. The terminal leafy rosette of the young plant is well formed before its basal roots appear, in striking contrast to the stolons of Bromelia which, under either aerial or subterranean conditions, form roots only at the base of the apical plantlet, and to the suckers or rootstocks of Ananas, which are relatively short and bear nodal roots. Aerial stolons are sometimes formed by Pseudananas (e.g., at San Bernardino, Paraguay) and in such cases act as those of *Bromelia*. The stolons of *Pseudananas* were found to decay earlier than those of Bromelia. These characteristic features supply an accurate field method of generic separation of non-fruiting plants, a task otherwise often extremely difficult.

<sup>7</sup> Of the most common bromeliaceous associates of these genera, Bromelia is spaced in the manner of Pseudananas,

and Aechmea is similar to Ananas.

A habitat similar to that reported by Bertoni (1919). <sup>9</sup> Corroborates the statement of Bertoni (1919).

A. bracteatus and A. ananassoides are crossed with a cultivated A. comosus, some of their progeny show adaptability to contrasting habitats unfavorable to many cultivated varieties, but resembling the natural environments of their respective wild parents.

#### SUMMARY

Evidence is presented that *Pseudananas* and most species of *Ananas* are native to that area of South America between 14° and 29°S. latitude and east of 59°W. longitude.

From exploration and study of herbarium material the distribution of species of *Pseudananas* and *Ananas* has been determined. *P. macrodontes* was found principally in the moist lowland forests of the Paraná-Paraguay Basin. *A. ananassoides* occurred in the dry, poor soils of the serrado of the Brazilian Planalto. *A. bracteatus* was observed in the better agricultural areas of the Rio de Janeiro-São Paulo

section and on the Alto Paraná, growing in moist soil at the margins of tree clumps; data on its natural distribution is limited because of prevalent agricultural practices and inadequate botanization. The habitat of A. erectifolius is probably the lowland rain forest of the Amazon drainage.

P. macrodontes was contiguous with A. ananassoides in southeastern Matto Grosso and with A. bracteatus in northeastern Argentina and southeastern Paraguay. The latter two species occurred together in the Rio de Janeiro-São Paulo region of Brazil. A central area common to all may be found with adequate botanization of the Brazilian states of Paraná, Santa Catharina, and parts of São Paulo. Clarification of the distribution of A. erectifolius awaits exploration of the southern side of the Amazon drainage.

# EXPERIMENTS ON BUD INHIBITION WITH INDOLE-3-ACETIC ACID <sup>1</sup>

## Folke Skoog

RESULTS OBTAINED by several workers with numerous species have established that correlative inhibition, as for example, the inhibition of the development of lateral buds by the terminal shoot in Vicia and Pisum, is due to auxin produced in relatively high concentrations by the inhibiting organ (Thimann and Skoog, 1933, 1934; Müller, 1935; Dostal, 1936). However, no agreement has been reached as to the action of auxin in inhibition. Ten different mechanisms have been proposed (ref. Thimann, 1939). These fall mainly into two groups according to whether auxin is considered to act directly in the inhibited organ (concentration effect, Thimann, 1937) or indirectly through affecting the availability or the translocation of nutrients to the inhibited organ (Laibach, 1933; van Overbeek, 1938) or the mobilization of more specific growth factors (Went, 1936, 1939; Ferman, 1938). An alternative indirect mechanism postulating that an inhibiting substance is formed under the influence of auxin has been proposed by Snow (1937).

Since the evidence is not conclusive for any of the above mechanisms, the question of whether the ac
1 Received for publication July 19, 1939.

tion of auxin in inhibition is direct or indirect has been further investigated.

MATERIALS AND METHODS.—Embryos of Pisum, variety Alaska, were prepared and grown under sterile conditions. The seeds were immersed in 0.1 per cent mercuric chloride solution for 20 to 30 minutes, rinsed, and allowed to soak in water for about 12 hours. They were then dipped in 90 per cent alcohol and rinsed in water immediately before removal of the embryos. The buds were cut with a sharp knife in the hypocotyls well above the cotyledonary axils, so that no root or cotyledonary tissues adhered. They were grown usually in lots of 3 in 125 cc. Erlenmeyer flasks containing 40 cc. of White's (1938) nutrient solution.2 Indole-3-acetic acid was supplied separately to prevent a possibility of its inactivation by heat. It was prepared by dissolving a given weight of crystals in peroxide free ether, evaporating to dryness in a sterile flask, and taking up in a given volume of water. A series of dilutions were made, and 1.0 cc. of the desired con-

 $^2$  Prepared according to White's suggestion with slight modifications in salt concentrations, with only one amino acid (glycine,  $^2$  mg./l.) and with 0.1 mg./l. vitamin  $B_1$ .

centration was added to each culture flask. To the controls was added 1.0 cc. of water. Since the preparation of the cultures required several hours, buds removed early and late were distributed equally among the different sets of an experiment. The initial lengths of the buds after transference to the solutions varied from 2.0 to 3.5 mm., but more than 90 per cent were between 2.5 to 3.0 mm. long. The buds were grown in a high humidity dark room at 25°C. and were exposed to light only at intervals for measurement of their lengths. Measurements given below are based on means of from 12 to 16 plants, which numbers have been found satisfactory for the periods of growth to be considered. An estimate of the reproducibility of results may be gained from some duplicate sets which are included.

RESULTS.—The buds grew for periods of at least four weeks with a constant or increasing growth rate and in no case with a decreasing average growth rate, although individual plants might show a decrease, and the rates were always less than would have been obtained in the presence of seeds. Whatever factors are needed for continued growth are therefore either supplied by the nutrient solution or are present in the buds for the duration of the experiments. Consequently, this material offers an opportunity to determine effects of auxin on growth

exerted directly in the buds.

The effect of different concentrations of indole-3acetic acid on the growth in length of the buds is indicated by results of an experiment in figure 1. In the first few days usually all treated plants grew less than the controls. Thereafter, those with the lower concentrations grew as fast or somewhat faster than the controls, whereas the plants with higher concentrations remained strongly inhibited for longer periods. For the purpose of demonstrating an inhibiting effect of applied indoleacetic acid the cultures need be grown for only a few days, and this early inhibition is considered below. However, in order to observe the effect of the treatments on subsequent growth, the cultures were kept for longer times. With concentrations below about 0.1 mg./l. of indoleacetic acid, the lengths and fresh weights of the treated plants would approach the values for the controls within four to six weeks, but with higher concentrations present continuously the final measurements remained less than those of the controls. If, on the other hand, plants were supplied with the higher concentrations, 10.0 and 0.1 mg./l., respectively, for shorter intervals, no permanent decrease in growth occurred. Results of one such experiment are presented in table 1. It may be seen that after exposure to even the 10.0 mg./l. solutions for as long as 65 hours, the buds subsequently grew as much as the controls, and after exposure to this concentration for a week, they still showed an increased growth rate upon removal but did not reach the final lengths or fresh weights of the controls. Thus the inhibiting effect of indoleacetic acid obtained during the first few days after application is reversible over a wide range of concentrations and is not due to injury or toxicity.

The above data further indicate that the application of very dilute solutions of indoleacetic acid continuously or of stronger solutions for short intervals resulted in a stimulation of bud growth. This effect was present in four out of six experiments but appeared in the late stages when the differences in

length of the individual plants were large, so that a statistically significant increase was obtained only in one case. An additional experiment with a few treatments of from 40 to 60 plants each also failed to show a real increase within 25 days. If the stimulating effect observed is real, its presence must require some condition as yet not adequately controlled. In any case, the increase was never so large as, and is probably not comparable with, the stimulation of bud growth obtained by Went (1939) by the ap-

plication of weak auxins to the stems of decapitated Pisum plants.

The present experiments show, nevertheless, that a reversible inhibition of bud growth is produced consistently by the proper concentrations of indole-acetic acid under conditions where the effect cannot be due to a diversion of nutrients or growth factors from one organ to another but must be exerted in the inhibited organ itself.

A brief reference to root development is made in this connection. No roots were present on any plants during the first week in which the marked inhibition of bud growth, considered here, was obtained. Most plants developed one or more adventitious roots within the second or third week. Usually, as indicated in table 2, the intermediate concentrations of indoleacetic acid led to a definite increase in the number of roots formed and a decrease in root elongation. The lower concentrations tended to hasten, the higher to delay, the time of appearance of roots. In cultures remaining after six weeks, however, some

roots had been formed in all but the 10 mg./l. concentration. The appearance of roots may contribute to a subsequent acceleration of growth of the stems. Data presented in table 3, obtained from 16-day-old cultures, show that plants with roots are in general longer than those without roots, but also some of the latter are longer than the average. Thus, inhibition of bud growth by indoleacetic acid is obtained in the absence of roots. The roots do not appear and are not essential for continued growth in length of these buds for a period much longer than required to demonstrate a marked inhibiting effect. It is concluded that roots can be disregarded entirely in a consideration of the inhibiting action of indoleacetic acid in the present experiments.

The inhibition of buds obtained here is directly comparable with that obtained by the application of auxin in lanoline paste directly to lateral buds of decapitated *Pisum* plants (Thimann, 1937). It is due principally to a reversible inhibition of growth of the entire organ rather than to a redistribution of

growth among its component tissues, although within a range of the weakly inhibiting concentrations a considerable growth in thickness may occur. The inhibition in the present experiments was never complete even with the higher concentrations, but this might be due merely to the fact that the buds

had started to grow before the indoleacetic acid was added so that its effect would be less; this is true also for lateral buds (Thimann and Skoog, 1934; van Overbeek, 1938). What growth did occur was limited to the lowest internode, which, nevertheless, remained much shorter than in the controls. There is, therefore, no evidence that the function of applied auxin in the inhibition of excised buds differs in any essential respect from that in the inhibition of buds on decapitated plants, although important secondary differences may exist. On the contrary, the following evidence indicates that the function is the same in the two cases.

Auxin has been demonstrated to cause inhibition of lateral bud development only when applied to stems in relatively high concentrations and only under conditions where it may reach the buds. Since the latter point has an important bearing on various proposed mechanisms of bud inhibition, some data will be presented regarding the effectiveness of indoleacetic acid applied to various positions of the stem. As shown by the results of two experiments (table 4), which have been repeatedly confirmed, concentrations of 2 or 4 mg. per gram of lanoline paste applied to stems of decapitated Pisum, grown in the dark, were completely effective in inhibiting the development of lateral buds for seven days when applied to the cut surfaces and also about 70 per cent effective when applied immediately below the cut surfaces; on the other hand, they were without any inhibiting effect when applied to the stems below the lateral buds. In other experiments, plants were treated with plain lanoline or auxin pastes below the lateral buds, and later the developing buds were decapitated or removed. In the control plants cotyledonary buds then developed, but in the treated plants only secondary lateral buds grew out. The treatment, therefore, was effective but only below the point of application. When, on the other hand, the basal treatments were with aqueous solutions, from which upward movement of the indoleacetic acid is facilitated through transport in the xylem, inhibition of the lateral buds above the point of application was obtained. The failure of the basal applications in lanoline paste must therefore be ascribed to insufficient upward movement of the substance to reach the buds, due to the existing polarity of transport in the stem. The same conclusion may be drawn from observations on the development of lateral buds in ringed plants.

Snow (1937), however, has shown that in a stem split lengthwise, so that auxin produced by a growing shoot must move acropetally to reach the lateral bud, the latter was nevertheless inhibited. On the basis of this and his earlier findings indicating that the extent of inhibition of lateral buds increases with distance from the apex, he has proposed that

the action of auxin is not direct but is due to the formation in its presence of an inhibiting substance which moves unrestrictedly through the plant causing inhibition where it is present in relatively large proportion to the auxin. The distance effect has been supported by Went's experiments in which weakly inhibiting concentrations of auxins were applied to cut surfaces of Pisum stems decapitated at different distances from the buds. But he interprets the effect as due to the attraction of growth factors away from the buds to the points of auxin application. Went further showed that slightly higher concentrations were effective whether applied to long or to short stems, and he confirmed the earlier observation (Thimann, 1935) that auxins which are less readily transported through the plant are effective only when applied near to the buds. The latter findings, as well as the data in table 4, are not in agreement with the theory of Snow in its present form,3 nor do they support the diversion theory of Went.

Results of a different nature presented in part in table 5 are also in disagreement with these mechanisms. A series of concentrations of indoleacetic acid in lanoline paste were applied to cut surfaces of decapitated Pisum stems in the dark, under which conditions apical swellings of the stems resulted from the treatments. However, in the upper range of concentrations where the extent of bud growth was affected relatively little, there were still large increases in the size of stem swellings, so that apparently bud inhibition may be very marked when there is only a partial mobilization of growth factors toward the apex. It was found, further, that when the plants of each concentration were considered separately, the plants with the biggest swellings had also the longest buds-i.e., a positive correlation exists between size of swellings and length of buds. On the

3 An inhibitor which is evidently an auxin complex has

recently been reported (private communication, Calif.

Inst. of Technology).

basis of diversion theories postulating that inhibition of buds results from a depletion of food factors in the auxin induced growth of the stem, a negative correlation would be expected. On the basis of Went's diversion theory a positive correlation can be expected only on the assumption that entirely separate limiting factors are involved in the production of swellings than are required for bud growth, and further, that in a given plant the presence of large amounts of the former factors is associated with relatively large amounts of the latter.

Finally, both the above theories fail to account for the very general phenomenon of bud inhibition in geotropically stimulated stems, where bud development is confined mainly to the upper sides even though auxin is derived from both sides and is present in higher concentrations on the lower sides of the stems.

In these diverse cases a direct action of auxin in the inhibited organs offers a plausible explanation, except for the inhibition of one developing shoot by another. In this case the latter mechanism appears insufficient but may not be so in fact if the inhibition is not merely a concentration effect. The experiments of van Overbeek (1938) and Ferman (1938) strongly indicate that in correlative inhibition the function of auxin cannot be ascribed to its concentration alone, but that some additional factor must be included in formulating a mechanism of general application. The present experiments, however, show that indoleacetic acid can inhibit the growth of excised buds, and they permit the deduction that this action of auxin directly in buds is probably of general occurrence, whether or not the effectiveness of auxin in correlative inhibition is limited to concentrations higher than required for growth, whether it is influenced by an effect on translocation, or whether it is determined by other factors.

#### SUMMARY

Excised buds of *Pisum* cultured in White's nutrient solution continue to grow in the dark for periods of several weeks. They therefore offer an opportunity to determine effects of auxins exerted directly on buds.

Indole-3-acetic acid was added to the nutrient solutions in concentrations from 0.0006 to 10.0 mg./l. All but the lowest concentrations inhibited the growth of the buds very markedly during the first few days after application. The inhibition obtained during this time was reversible and was not due to toxicity.

The weak and also the stronger solutions perhaps caused a subsequent stimulation of growth if the buds were transferred from the latter to plain nutrient solutions after short periods, but if the buds were kept in solutions higher than 0.1 mg./l., they

remained shorter than the controls for the duration of the experiments.

Further experiments with *Pisum* seedlings and other evidence are presented which indicate that auxin applied to stems also must reach the lateral buds to inhibit their growth.

It is concluded that even though the inhibiting action be not explainable in terms of concentrations alone, indoleacetic acid can inhibit growth directly in buds; and that whether or not the effectiveness of auxin in correlative inhibition is influenced by an effect on translocation of nutrients or by other factors, auxins applied to decapitated stems probably generally exert an inhibiting action in the lateral

## SEX CHROMOSOMES OF CANNABIS SATIVA 1

## Elizabeth L. Mackay

Cannabis sativa was reported by Strasburger (1909, 1910) to have no sex chromosomes. He showed the haploid number to be 10, the somatic number 20. McPhee (1924) likewise found no sex chromosomes. Working with two Japanese varieties of hemp, Hirata (1924, 1929) observed an unequal pair of chromosomes in the metaphases of the heterotypic division in pollen mother cells. Since no unequal pair was found in the female, but instead an equal pair slightly larger than the other chromosomes, he assumed this large pair in the female to be an XX and the unequal pair in the male XY. The presence of an unequal pair in Cannabis was con-

<sup>1</sup> Received for publication August 5, 1939.

The writer wishes to express her appreciation to Professor C. E. Allen for his helpful criticism in the preparation of this paper. Part of the research was done in the Department of Botany, University of Wisconsin, Madison, Wisconsin.

firmed by Sinotô (1928, 1929). Driga (cited by Hoffmann, 1938), investigating a large number of races, found in the male an unpaired three-parted chromosome together with a two-parted chromosome.

Sex chromosomes have not been clearly distinguished in somatic cells. Breslawetz (1932) saw, in somatic divisions in the root tip, one large chromosome which she named the X and another with a median constriction which was smaller than the X but larger than the other chromosomes; this she identified as the Y.

In view of the discrepancy between the observations of Strasburger and McPhee on the one hand, and those of Hirata and Sinotô on the other, it has been suggested by various writers (e.g., Hoffmann, 1938) that varieties of hemp may differ in that some possess and some lack sex chromosomes. Because of

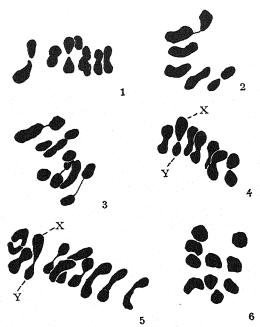

Fig. 1-6. Cannabis sativa.—Fig. 1-5. Lateral views of meta-anaphases of the first meiotic division of pollen mother cells. XY pair of unequal size.—Fig. 5. Aceto-carmine preparation showing unequal pair.—Fig. 6. Polar view of metaphase showning n=10.—Fig. 1-4, 6,  $\times$ 3650. Fig. 5,  $\times$ 3000.

this uncertainty, and particularly since no report has appeared of the occurrence of an XY pair in

American races, it seemed worth while to undertake the study reported in the present paper.

Material of staminate buds was fixed from two different wild stands of hemp in or near Madison, Wisconsin, and from one cultivated variety which was obtained from Professor A. H. Wright of the Agronomy Department of the University of Wisconsin. In favorable lateral views of the metaphases and anaphases of the first meiotic division in pollen mother cells of plants from each location, an unequal pair of chromosomes was very evident (fig. 1-5). Ten pairs of chromosomes are present, as described by the earlier workers already cited. Nine pairs are similar in size, each being composed of equal members. The tenth pair (XY) consists of one chromosome of about the same size as the members of the other nine pairs, and one much larger chromosome.

It is evident that this unequal pair is the sex chromosome pair. From the number of varieties from various parts of the world now known to possess an XY pair it is highly probable that this condition prevails in all varieties of *Cannabis sativa*.

#### SUMMARY

An unequal (XY) pair of sex chromosomes is present in staminate plants of probably all varieties of Cannabis sativa.

# THE RELATION OF pH AND TEMPERATURE TO THE FRUITING OF PHYSARUM POLYCEPHALUM<sup>1</sup>

William D. Gray

THE FACTORS initiating and influencing the formation of fruiting bodies of myxomycetes have been considered by several workers, and various reasons have been advocated as being responsible for this process. Harper (1914) has shown that plasmodia of Didymium melanospermum (Pers.) Macbr. lose water when about to fruit, and for this reason Skupienski (1920) stated that sporangial formation is the result of desiccation and that small plasmodia will fruit more quickly than large plasmodia because they may lose water more easily. It is rather doubtful that such is the case, because Harper specifically pointed out that this desiccation is not simply the drying out of a colloidal mass but is probably due to the forcible extrusion of water from the protoplasm; this extrusion of water he thinks may be brought about by condensation processes involving changes from highly hydrated proteins to lipoid or other fatty storage products. The work of Constantineanu (1906) would also tend to discredit Skupienski's view, since this worker showed that plasmodia of Physarum didermoides (Ach.) Rost. and Didymium squamulosum (Alb. & Schw.) Fr. (D. effusum Link) would form fruiting bodies if the substratum was moist but would encyst if it was dry. Camp (1937) has shown that plasmodia of Physarum polycephalum Schw. may be induced to fruit if they are starved. This is easily demonstrated for this species and may be the factor largely responsible for some fruitings in nature; however, since most naturally occurring fruitings (and this is particularly true for forms that grow on wood) are to be found closely associated with easily available food material, we must look to other factors for the initiation of the fruiting process. In an earlier paper by the writer (Grav, 1938) it was pointed out that in general, light is necessary for fruiting of several yellow-pigmented plasmodial types. It is the purpose of the present investigation to determine the influence of the factors of pH and temperature upon fruiting. Other factors are undoubtedly also involved, since during its plasmodial stage a myxomycete consists simply of a mass of protoplasm, unprotected by any type of cell wall, and would naturally be expected to be extremely sensitive to numerous environmental factors.

MATERIALS AND METHODS .- Because of the ease with which it may be cultured, Physarum polycephalum Schw. was used as the experimental organism. Starved cultures were used in all experiments, since

Received for publication August 17, 1939.

The writer is indebted to the National Research Council for a Fellowship which made this work possible. He also wishes to express his appreciation to Prof. B. M. Duggar, Department of Botany, University of Wisconsin, under whose sponsorship this research was conducted.

fed cultures are far too cumbersome to permit the handling of many in a single series. The difficulties to be encountered in the handling of numerous fed cultures simultaneously are obvious in view of the fact that one plasmodium may well fill a ten-inch culture dish within a few days. Starved cultures were prepared in moist chambers consisting of inverted embryological staining dishes (4  $\times$  4  $\times$  1.5 cm.), covered with porous towel paper, and placed in 500 cc. lipless beakers, to each of which 30 cc. of distilled water or buffer solution had been added. After small bits of plasmodium had been placed in each of the moist chambers, cellophane was placed over the top of each beaker and fastened by means of rubber bands. All cultures used in the following experiments were inoculated from five or six day old stock plasmodia which had been maintained in complete absence of light. Stock cultures were maintained in large culture dishes in the manner suggested by Camp (1936); such cultures were fed by sprinkling with rolled oats and presumably received an abundance of all the elements essential for their growth. Inoculations were made approximately twenty-four hours after the last feeding of stock plasmodia.

For the maintenance of various pH values in the moist chambers, the dibasic sodium phosphate-citric acid buffer mixtures recommended by McIlvaine (1921) were used; these were diluted 1:10. Such buffer solutions were always checked with the Beckman glass electrode. Values ranging from pH 3.0 to pH 8.0 (at intervals of one pH unit) were used.

Constant temperature was obtained through the use of a large tank of water, beakers being immersed in the water to a depth of about 5 cm. This tank was equipped with heating bulb, thermal regulator, stirrer, and a large copper coil through which tap water could be circulated. Cultures placed in the water bath were continuously exposed to light from a 300 watt incandescent bulb suspended one meter above the tank. Experiments were conducted at 21.0°, 25.0°, 27.5°, 30.0°, 32.5°, and 35.0°C. in the water bath; for checks which were run in complete absence of light, a small electric oven was employed. In addition to cultures maintained at the temperatures mentioned above, several hundred cultures were placed in the dark in a refrigeration room where the temperature generally remained at 8.0°C., although it sometimes rose as high as 12.0°C.

In the data presented in this paper, it will be noted that all figures expressing hours required for fruiting or for killing are averages taken from a number of cultures. In order to express the variation within each series, all data were analyzed by standard statistical methods, and with each average the probable error of the average is also listed.

INFLUENCE OF PH UPON FRUITING.—Preliminary experiments using cultures maintained at pH values ranging from pH 3.0 to pH 8.0 were run at 25.0°C., and it was found that a higher percentage of cultures fruited at the lower pH values (3-5) and also that less time was required for fruiting. Fruiting bodies appeared in cultures maintained at pH values ranging from pH 3.0 to pH 7.0, but in no case was fruiting obtained at pH 8.0. Few observations have been made concerning the effect of pH on myxomycetes, but the above findings are in general agreement with the findings of other workers. Howard (1931), when first describing methods for the culture of P. polycephalum, stated that plasmodia seem to prefer a slightly acid medium and will tolerate an acidity on oat agar as great as pH 4.8; the present work reveals that this species will tolerate a much greater acidity when starved cultures are used. Jahn (1932), referring to a species of Badhamia, which he cultured on agar with a decoction of Polyporus versicolor, observed that plasmodia showed injury when the pH of the medium was below pH 4.0 or above pH 7.5. Perhaps the most extensive observations on the effect of pH on fruiting were made by Emoto (1938), who collected about 4,000 different fruitings (consisting of 106 different species and varieties of myxomycetes from decaying wood representing 76 species of woody plants) and found that in most cases the reaction of the substratum was pH 4.2-5.8. Of these 4,000 fruitings, only 10 were found on substrates where the reaction was higher than pH 7.0. From the work of Smart (1937) it is apparent that an acid medium is also more favorable for spore germination; this worker conducted studies on spore germination with 70 species and varieties of myxomycetes and found that the optimum in all cases was between pH 4.5 and 7.0.

INFLUENCE OF TEMPERATURE UPON FRUITING .-In regard to the effect of temperature upon fruiting few observations have been made. It is to be expected that different species might have different optimum temperatures, and the reports of various workers would tend to bear this out. For example, Howard (1931) stated that the optimum temperature for P. polycephalum is between 20.0° and 26.0°C., whereas Skupienski (1934) found that the optimum temperature for Didymium xanthopus (Ditm.) Fr. is 10°-12°C. Constantineanu (1906) reported fruiting by P. didermoides at 8°-12°C. and in Fuligo septica (L.) Weber [Aethalium septicum (L.) Fr.] at 25° and 35° but did not state the optimum temperature for fruiting of these species. Skupienski also pointed out that physiologic strains may exist and showed that while the optimum temperature for D. xanthopus is 10°-12°C., a strain of the same species which he terms var. thermophilum (not used in a systematic sense) has its optimum at 25°C.

INTERRELATIONSHIP OF PH AND TEMPERATURE IN RESPECT TO FRUITING.—Shortly after this work was begun it became apparent that in their effects upon fruiting the factors of pH and temperature are

rather closely related and either may be considered a limiting factor with respect to the other. Results of experiments in which this interrelationship is considered are presented as follows:

Series I. Temp. =  $21.0^{\circ}C$ . (110 cultures).— Since Howard stated that the optimum temperature for P. polycephalum is between 20.0° and 26.0°C... the first of the present series was conducted within this temperature range. As stated before, pH values at this temperature, and all subsequent ones, ranged from 3.0 to 8.0 at intervals of one pH unit. At the first four pH values fruiting bodies were formed in all cultures, at pH 7.0 fruiting occurred in 60 per cent of the cultures, and at pH 8.0 sporangia appeared in only 55 per cent of the cultures. The average time required for fruiting (time being measured from the time of inoculation to maturing of fruiting bodies) was 30.1 hours at pH 3.0, dropping to 26.4 hours at pH 4.0, and gradually rising to 33.1 hours at pH 8.0.

Series II. Temp. =  $25.0^{\circ}$ C. (105 cultures).—No fruiting was obtained at pH 8.0 when cultures were maintained at this temperature. As in the preceding series, 100 per cent fruiting occurred in cultures conducted at pH 3.0 and pH 4.0; percentage fruiting then decreased from 93.3 per cent at pH 5.0 to 13.3 per cent at pH 7.0. At each pH value the average time required for fruiting was longer at this temperature than at 21.0°C.; for example, at 21.0° the average time for fruiting in cultures at pH 3.0 was 30.1 hours, while at 25.0°, at the same pH, the time required was 30.3 hours, a very slight difference to be sure, but probably quite valid since much greater differences were exhibited at higher pH values. As in Series I, fruiting at pH 4.0 required the least amount of time.

Series III. Temp. = 27.5°C. (146 cultures).—Cultures were run at the same pH values as in the preceding series, but fruiting was obtained only at pH 3.0, 4.0, 5.0, and 6.0. At pH 3.0 sporangia appeared in all the cultures, the percentage of cultures fruiting then decreasing with rise in pH value to only 77.3 per cent at pH 6.0. Cultures at pH 4.0 required the least time for fruiting, and at each pH value a greater time was required for this process than was required by similar cultures in the preceding series. The differences in time required for fruiting were in general greater between this series and Series II than between Series I and Series II; these differences are shown in table 1.

Skupienski (1930) has shown that variations in temperature produce profound changes in the structure of fruiting bodies of  $Didymium\ nigripes$  (Link) Fr., and it is interesting to note that similar morphological changes undoubtedly occur in sporangia of P. polycephalum. Although detailed observations of the structure of sporangia obtained in these experiments were not made, it should be noted that in this series ( $T=27.5^{\circ}$ ) and in all series where higher temperatures were involved, many sporangia were either extremely short-stipitate or sessile. More careful observations on this point will be made later.

Table 1. Differences in hours required for fruiting between Series I and Series II and between Series II and Series III.

pH	3.0	4.0	5.0	6.0	7.0	8.0
Series I, T = 21°	30.1	26.4	26.5	29.3	30.7	33.1
Series II, T = 25°	30.3	29.2	31.1	34.9	49.0	
Difference	0.2	2.8	4.6	5.6	8.3	٠
Series II, $T = 25^{\circ}$	30.3	29.2	31.1	34.9	49.0	٠.٠.
Series III, T=27.5°.	36.1	32.6	35.8	45.5		
Difference	5.8	3.4	4.7	10.6		

Series IV. Temp. = 30.0°C. (175 cultures). No mature fruiting bodies were obtained at this temperature at pH values higher than 5.0, although in some cultures at pH 6.0 sporangia were formed; these sporangia, however, never matured and are referred to in table 2 and elsewhere in the paper as "attempted fruiting." Percentage fruiting at pH 3.0 was 87.8 per cent as compared with 80.0 per cent at pH 4.0 and 47.2 per cent at pH 5.0. As in all the preceding series, cultures at pH 4.0 fruited in less time than cultures at pH 3.0 and pH 5.0 but required a longer period of time than similar cultures run at 27.5°. Table 2 shows the relationship of pH and temperature to fruiting in so far as percentage of cultures forming sporangia is concerned, while table 3 shows this same relationship with respect to time required for fruiting. Figure 1 illustrates the curves of fruiting derived from the data in table 3.

Series V. Temp. = 32.5°C. (207 cultures).— At this temperature sporangia were formed only in cultures maintained at pH 3.0 and 4.0, although

HOURS REQUIRED FOR KILLING

Fig. 2 (below). The effect of pH upon rate of killing of plasmodia maintained at high temperatures.

rangia appeared in 68 per cent of the cultures at pH 3.0, in 66 per cent at pH 4.0. Since this temperature is definitely lethal except at the two lowest pH values, a record was kept of the length of survival of the various cultures in order to determine if any relationship existed between pH and hours required for killing. The curve of killing obtained from these

figures is shown in figure 2; data for the two lowest values were obtained from the 32 per cent that were killed at pH 3.0 and the 34 per cent that were killed at pH 4.0. A plasmodium was judged dead when the plasmodial veins began to lose their identity and the color changed from yellow to reddish-brown. In general it may be said that, within the range tested, the higher the pH the quicker plasmodia are killed. In no case did sclerotia formation result from such treatment. Plasmodia of this species obviously can stand somewhat higher temperatures than some other species, since Klebs (1900, p. 138) reported that plasmodia of Didymium difforme (Pers.) Duby form sclerotia at 25°-26°C. but decomposed at 30°C. Either D. difforme is less tolerant of higher temperatures than is P. polycephalum or else the medium upon which Klebs grew his plasmodia was so basic that they were more susceptible. The first hypothesis is the more feasible, because in the present work high pH combined with high temperature did not induce the formation of sclerotia.

Series VI. Temp. = 35.0°C. (157 cultures).—At this temperature fruiting could not be obtained, regardless of the pH at which the cultures were maintained. It is true that attempted fruiting did occur at pH 3.0, but, as in other cases of this nature, no sporangia were ever matured. Killing of plasmodia followed the same general pattern as at 32.5°. Numerical data for each series are presented in table 4, while curves derived from these data are shown in figure 2.

EFFECT OF PH UPON FRUITING IN DARK.—In an earlier paper by the writer (Gray, 1938) it was stated that in general yellow-pigmented plasmodia require light in order to complete their life cycles. This is particularly true for fed cultures, where fruiting without light occurs rarely. The incidence of fruiting of starved cultures in the dark was higher than in fed cultures, so the possibility existed that

the necessity of light for fruiting might be dispensed with in starved cultures if such cultures were placed in an environment where all the other factors were favorable for fruiting. It is to be noted that throughout all the preceding series, a higher percentage of cultures formed fruiting bodies at pH 3.0 than at the higher values; therefore cultures were conducted at this pH in the dark at various temperatures in order to determine if light could be dispensed with. Checks were maintained in moist chambers containing distilled water. The results of these studies are presented in table 5.

From the results of table 5, we can safely conclude that even in starved cultures light cannot be entirely dispensed with by lowering the pH to 3.0, which value produced fruiting in the greatest percentage of cultures in the light. It would seem that in the complete absence of light, high acidity has a definitely unfavorable effect, because at 25.0°C. 13 per cent fruiting was obtained in cultures containing only distilled water, while only 8.2 per cent fruiting was obtained with cultures maintained at pH 3.0. Perhaps the statement that light is a necessary factor may be considered somewhat broad in view of the fact that some fruitings do occur in the complete absence of light; however, a comparison of the figures in table 5 yields the general picture that light is the important factor.

Since, within the range tested, higher temperatures produced unfavorable effects in so far as percentage fruiting and hours required for fruiting are concerned, the possibility existed that perhaps lower temperatures might produce effects that would overcome the necessity of light for fruiting. Cultures were then placed in the dark in a refrigeration room where the temperature varied from 8°-12°C. One or two cultures were removed every twenty-four hours and placed in light at a temperature of 25.0°C. in order to determine if they were alive; this was judged by whether or not streaming was resumed.

Table 5. The effect of pH and temperature upon percentage fruiting in light and in dark. Figures in parentheses indicate the number of cultures in a series.

Temperature	Medium used in moist chamber	Light	Dark
25.0°	Distilled water Buffer at pH 3.0	96.0% (100) 100.0% (100)	13.0% (100) 8.2% (85)
80.0°	Distilled water Buffer at pH 3.0	87.8% (30)	18.0% (50) 3.3% (25)
85.0°	Distilled water Buffer at pH 3.0	0.0% (35) 0.0% (40)	0.0% (100) 0.0% (20)

Plasmodia persisted for considerable periods at 8°-12° but eventually succumbed without fruiting. The rate of killing with respect to pH follows the same general pattern as at the higher temperatures, as may be seen in table 6.

Table 6. The relation of pH to rate of killing of plasmodia at 8°-12°C.

	Days required	
pH	for killing	No. of cultures
3.0	16	35
6.0	10	20
8.0	2	20

Various workers have pointed out that low temperatures induce formation of sclerotia. For example, Klebs (1900) and Constantineanu (1906) both state that D. squamulosum encysts at 1°-2°C., and the latter worker also states that the same is true for Badhamia macrocarpa (Ces.) Rost. DeBary (1864) makes the general statement that a decrease in temperature promotes sclerotia formation. No sclerotia formation was observed in the present work with P. polycephalum, although 241 cultures were involved in the experiments conducted at 8°-12°C. It is true that many plasmodia clumped into a solid mass of protoplasm at this temperature, but there was no apparent loss of water, and certainly these clumps could not be termed sclerotia.

Discussion.—From the foregoing experiments which involved observations on 2,030 different cultures, we may arrive at several general conclusions. First, we may set the optimum temperature for Physarum polycephalum at 20°-21°C., although more will be said about this later. Howard set the optimum for the species at 20°-26°C., but the writer has found that a higher percentage fruiting occurred at 21.0°C. than at higher temperatures; therefore the optimum is set between the lowest value given by Howard and the lowest tested by the writer. Very little difference occurs in length of time required for fruiting at 21°, regardless of pH value, as is shown in the curve of fruiting in figure 1; it will be noted that the curve for this temperature approaches a straight line. The highest temperature at which fruiting may occur is between 32.5° and 35.0°C. Temperatures as high as these are for the most part lethal, and there is a definite relationship between degree of acidity and length of life at a lethal temperature: the lower the pH (between 3.0 and 8.0) the longer the survival. At 35.0° plasmodia in moist chambers, in which the buffer solution is at pH 3.0, survive on the average for three days or more, while similar cultures at pH 8.0 are killed in seven hours

Concerning the relationship of pH to temperature in regard to fruiting, it may be said that the higher the temperature, the lower the pH must be in order to permit sporangia formation. At 32.5° the pH of the solution in the moist chambers must be as low as pH 4.0 or no fruiting will result; at 27.5°, the pH

must be 6.0 or lower, while at 21.0°, fruiting will occur at all pH values up to and including pH 8.0.

In the range tested, temperature remaining constant, the lower the pH the greater the chances are that a plasmodium will fruit as is evidenced by the results in table 2, which lists the percentage of cultures fruiting at various pH values over the temperature range examined. With pH a constant factor, the number of hours required for fruiting varies directly with temperature: the lower the temperature the fewer the number of hours required for sporangia formation.

In all the above series where fruiting was obtained, the least time was required for this process at pH 4.0; therefore we may conclude that the optimum pH for fruiting, with respect to time required, is somewhere near this value. However, the optimum pH for fruiting, with respect to percentage of cultures forming sporangia, was at pH 3.0 (with the exception of Series I and Series II, in which series 100 per cent fruiting was obtained at several of the lower pH values). Therefore, when an optimum pH value is stated, the criterion by which this is judged must be defined, since at one value fruiting is accomplished in the least amount of time, whereas at another value the chances that a plasmodium will fruit are greater. When stating an optimum temperature value, one should be careful that pH value has also been taken into account.

No evidence is obtained from the foregoing studies that sclerotia formation is favored by either high or low temperatures, provided the substratum is moist. Quite possibly there is an optimum temperature for formation of sclerotia, but it would seem that this process is more dependent upon proper

desiccation of the plasmodium.

The fact that higher temperatures (27.5° and above) bring about the production of sessile or short-stipitate sporangia within a species in which the fruiting bodies are normally markedly stipitate might cause one to wonder if perhaps some of the varieties and species now named might not be forms of other species which show variations because of changes in environmental factors. The work of Skupienski (1930) would tend to bear out this conjecture, although many more observations must be made before any definite conclusions are drawn.

### SUMMARY

The interrelationships of the factors of temperature and pH upon the fruiting of *Physarum polycephalum* Schw. have been studied, and from data derived from observations made on 2,030 cultures, the following conclusions are drawn:

The factors of pH and temperature are closely related and interdependent.

The higher the temperature at which a plasmodium is maintained, the greater the acidity must be in order to produce fruiting.

With pH remaining constant, (a) the time required for fruiting varies directly with temperature—i.e., the higher the temperature the longer the time

required for fruiting; (b) the percentage of cultures producing fruiting bodies varies inversely with temperature—i.e., the higher the temperature, the smaller the percentage fruiting.

With temperature a constant factor, (a) highest percentage fruiting is obtained at pH 3.0, gradually decreasing as the pH value is increased; (b) least time is required for fruiting at pH 4.0.

Maximum temperature at which P. polycephalum will fruit is between 32.5° and 35.0°C.

Length of survival of plasmodia at high temperatures is dependent upon pH value and varies in-

versely with it. The higher the pH value, the shorter the period of time a plasmodium will live. This same relationship exists for plasmodia maintained at low temperatures (8°-12°C.).

Under the conditions of the above experiments, sclerotia cannot be produced at high temperatures (32.5°-35.0°) nor at low temperatures (8°-12°).

Generally speaking, the necessity of light for fruiting cannot be dispensed with by increasing acidity nor by lowering the temperature.

## PLANTS USED BY THE ESKIMO OF THE NORTHERN BERING SEA AND ARCTIC REGIONS OF ALASKA <sup>1</sup>

### J. P. Anderson

During the summer of 1938, through the kindness of the U. S. Coast Guard, the writer was able to visit the Eskimo villages of Northern Bering Sea and Arctic Alaska. He wishes to express his sincere thanks to the officers and crew of the cutter "Northland," on which the cruise was made, and especially to Commander F. A. Zeusler, master of the vessel, and to Lieutenant Commander R. C. Sarrat, executive officer. The writer's chief object was to study the flora of the region and to collect herbarium specimens, of which some 2,100 numbers were secured; at the suggestion of Commander Zeusler, however, some inquiries were made regarding the plants used by the Eskimo, especially those used for food.

The information here presented was obtained to some extent from white school teachers and other white persons resident in the region, but for the most part direct from the Eskimos themselves. The time devoted to the work was very limited, and the subject is worthy of further study. The following notes, though incomplete, may, however, be of interest and may aid anyone wishing to study the subject further.

1 Received for publication September 1, 1939.

The diet of the Eskimo is almost exclusively of animal origin. The total portion that is directly vegetable is very small. The food plants growing in the vicinity of the villages indicated that but little had been gathered. Some exceptions to this rule are found in the Norton Bay region where gardens are grown to some extent, especially at Unalakleet where the Missionary has induced the Eskimo to grow fine gardens with a surplus for sale to boats and for shipment to the market at Nome.

Considering the small amount actually consumed, the number of native species used is surprisingly large; not all the plants listed here, however, are used everywhere they occur, and in some villages only a few seem to be used at all. A more detailed study would be desirable.

Various methods are employed in preparing the plant material for consumption. Some is eaten raw the same as we eat lettuce and celery. Some is simply scalded. Another method is to use either scalding or cold water and then allow the material to ferment, the preparation being ready for consumption when the proper stage of fermentation is reached. They

call this "souring" and sometimes add sugar to the soured material. Ordinarily the material is also boiled.

One of the commonest methods of use is to immerse the plant material in oil. In this way it may be preserved for winter use. On St. Lawrence Island whale blubber is mostly used, while on the mainland the Eskimo frequently uses seal oil; reindeer tallow may be used at times for the same purpose. Oil as used in this paper refers generally to seal oil.

All berries are eaten fresh, and most kinds are also preserved in oil. To a limited extent the Eskimo is learning the white man's methods, and there is a

tendency away from the old habits.

Among the monocotyledons, products of three species are consumed. The enlarged farinaceous bases of a sedge, Carex sp., are called mouse food from the custom of robbing the nest of field mice (Microtis), which gather them for winter food. In some places fish is placed in the mouse nests so that the mice may live through the winter and be able to store a new supply of the sedge the following year. Allium sibiricum L. is prepared by scalding. This species is closely related to the cultivated chives. The seeds of Iris setosa Pall. are roasted, ground, and used as coffee at a few places.

Several species of willow grow in every locality visited, but only one, Salix pulchra Cham., seems to be utilized as food. This species grows scarcely a foot high at Barrow, but the vigor increases southward so that it may attain a height of 6-8 feet at the mouth of the Yukon. The young shoots and catkins are used fresh and in seal oil and may be stored in the oil for winter use. The bark is also peeled off and

the cambium scraped off and eaten.

Alder (Alnus frutica Rupr.) is not secured for food, but the bark is used for dyeing reindeer skins.

Two of the Eskimo's most important food plants

belong to the Polygonaceae. They are Oxyria digyna (L.) Hill. and Rumex arcticus Trautv. The leaves are eaten fresh, soured, boiled, or in oil. The root of Rumex is also utilized, and it is probable that in some localities other species of Rumex than arcticus

are used.

The fleshy taproots of Claytonia acutifolia of the Portulacaceae are used on King Island and a few other places. The leaves of Ammodenia peploides major Hook, a fleshy beach plant belonging to the Caryopluylaceae, and of Rhodiola integrifolia Raf., a succulent of the family Crassulaceae occurring in rocky places, are eaten fresh, soured, or in oil. In some villages one was used but not the other, while in other villages both were used. The roots of Rhodiola are also sometimes procured.

Three species belonging to the Ranunculaceae are utilized. Anemone narcissiflora L. on King Island is used as we use cress and also soured or prepared in oil. Prepared in oil together with other salad greens and beaten to a creamy consistency, it is called cocpotac. This is much relished and when frozen is claimed to be the original Eskimo ice cream. It also has ceremonial significance. In some villages the leaves of Caltha asarifolia DC. are consumed fresh.

Rootstocks of Ranunculus Pallasii are used but become bitter when leaves develop.

Saxifrages are well represented in the flora of the far north, and one type, Saxifrage punctata L., is widely used by the Eskimo. It occurs not in the typical form, but it is represented by geographical races. The succulent leaves are eaten fresh or in oil. They may be preserved for long periods in oil.

Red currants (Ribes triste Pall.) are used where they occur in the Norton Sound region and further

inland northward.

Of the Rosaceae, the dried leaves of Potentilla fruticosa L. are used for tea at Nome. Rubus arcticus L., which intergrades with Rubus acaulis Michx., produces a red berry of very good quality which is here often called strawberry. The most widely distributed of this group of berries, however, is the Cloudberry or Baked-apple berry, Rubus Chamaemorus L., usually but improperly called salmonberry by the Eskimo.

The roots of the leguminous plants of the genus *Hedysarum* are procured. These become rather fleshy and farinaceous in the fall and are used the

same as potatoes.

The seeds of the Beach Pea, Lathyrus maritimus, are roasted and employed in making coffee.

The crowberry, Empetrum nigrum L., is very common, and the fruit is used to a limited extent and

often called Blackberry.

Young shoots of Fireweed (*Epilobium angustifo-lium L.*) are gathered and boiled, usually mixed with *Rumex*. If bacon is added, the dish is said to be delicious.

A species of Mares-tail, *Hippuris tetraphylla* L., furnishes small leaves that are eaten as greens when gathered while young.

At least two umbelliferous plants are used. Ligusticum hultenii Fern. is cut, mixed with fish, and

boiled for winter use. Coelopleurum gmelini (DC.) Ledeb. is used as the white man uses celery.

Bunchberries, Cornus canadensis L. and Cornus suecica L., are often gathered and mixed with other berries.

The Heather family furnishes several species that are utilized by the Eskimo. Cassiope tetragona (L.) D. Don is not a food plant but together with mosses and lichens is gathered for insulating the houses against cold. The Alpine Bearberry, Arctostaphylos alpina (L.) Spreng., is common but is not utilized to the same degree as some of the other berries. The blueberry, Vaccinium uliginosum L., mostly the variety alpinum Bigel., is one of the most important berries. At some Arctic villages the Eskimo must go up the rivers to find it. At Wainwright it is said to grow four miles inland. The Lowbush or Mountain cranberry, Vaccinium vitis-idea minus Lodd, is found on the tundra clear up to Barrow.

Labrador tea, Ledum decumbens (Ait.) Lodd, occurs all over the tundra and is generally used for tea. It is also supposed to have medicinal value. In some places the rootstock of Lungwort, Mertensia mari-

tima (L.) S. F. Gray, is eaten.

A species of *Pedicularis*, known to the Eskimo as Bumblebee plant, furnishes a root that is sometimes eaten and leaves that are soured.

Plants of Achillea borealis Bong. are dried and made into an infusion that has medicinal qualities. Artemisia sp. is also dried and used for medicine. It may be prepared as an infusion for colds, or the powdered plant may be made into poultices for injuries or swellings.

Sweet Coltsfoot, *Petasite frigida* (L.) Fries, is gathered as greens but to a limited extent only.

Dandelion, *Taraxicum* spp., is used in some places. The leaves are scalded.

An infusion made of the needles of White Spruce, *Picea canadensis* (Mill.) B.S.P., is used as medicine for all purposes. The resin is applied to wounds or chewed for pleasure. Its distribution is limited to Norton Sound and inland regions.

Mushrooms are reported as being eaten raw by the natives of St. Michael.

In addition to the above, two or three species were described to the writer which he was unable to locate.

Eskimo Names.—The writer is no linguist, and when he asked the Eskimos their native names for the plants used he found it very hard to find the proper letters to exactly represent the sounds given. The Eskimos of the region speak the same general language, but the dialect varies from village to village, and the region covered is large. In a few cases different names seemed to be used. Also different names are used for various parts of the same plant or for the same part prepared in different ways. Below are a few of these Eskimo names.

### SUMMARY

During the summer of 1938 the writer made a voyage to the Northern Bering Sea and Arctic coasts of Alaska on the U. S. S. "Northland," C. G., on a botanizing trip. Some inquiry was made regarding the use of native plants by the Eskimo; a list is given of 40 seed-bearing plants used by them, mostly for food.

# CHROMOSOME COMPLEMENTS OF FIVE SPECIES OF POA WITH AN ANALYSIS OF VARIATION IN POA PRATENSIS <sup>1</sup>

William L. Brown

Grass investigations in the past have dealt primarily with the taxonomic aspect. Recently, however, turf culture and soil conservation have created a need for a more thorough knowledge of the genetic constitution and interrelationships of the plants employed. This study, primarily concerned with variation in *Poa pratensis*, attempts to extend investigations beyond the realm of comparative morphology and to correlate with morphology evidence gleaned from cytological studies. Such a procedure seems necessary in order to arrive at a clearer understanding of the entities involved.

The genus *Poa*, considered usually as one of the more important groups of economic grasses, presents many difficulties from the standpoint of taxonomy and phylogeny. These are due to a number of factors, particularly the large number of species, wide distribution, and extensive cultivation. The taxonomic difficulty is evidenced by the disagreement regarding the position of several species within the genus, which is itself rather loosely held together by more or less arbitrary characters. Sections are in some cases delimited on vegetative characters, which, to say the least, are extremely variable.

The author wishes to express his appreciation to Dr. Edgar Anderson, under whose direction this work has been done, for suggestions and helpful criticisms offered throughout the course of the investigation. To Mr. R. L. Hensel, the author is grateful for the supply of living plants of *Poa arachnifera* from Texas.

MATERIALS AND METHODS.—Living material for cytological study, for the most part, came from the Missouri Botanical Garden Arboretum, Grav Summit. Missouri, and the Missouri Botanical Garden, St. Louis, Missouri. Plants were selected from well established sod, root tips taken from them, and the plants removed either to the garden nursery or greenhouse, depending upon the time of year at which they were taken from the field. In all cases they were brought into flowering, and herbarium specimens have or will be made from them for permanent records. In addition to the Missouri Botanical Garden plants, material from Green Bank, West Virginia, Schoolcraft, Michigan, Washington, D. C., Vanceburg, Kentucky, and College Station, Texas, has been examined. Plants grown from commercial seed from Mangelsdorf Seed Co. and Palmer Seed Co., St. Louis, Missouri, and Scott Seed Co., Marysville, Ohio, have also been examined. This seed, for the most part, came from the region around Kansas City, Missouri.

Root tips were fixed in La Cour's 2 BD or Navashin's fixative, the first always giving superior reults. Following fixation, the tips were run into paraffin according to the method described by La Cour

<sup>1</sup> Received for publication June 29, 1939.

(1931), then sectioned at  $12-15~\mu$ , and the sections stained with crystal violet. Metaphase plates were drawn with the aid of a camera lucida, after which the chromosomes were counted from the drawing. When there is any doubt as to the exact number of chromosomes present, this has been indicated by  $\pm$  1.

Chromosome numbers of four native species.—While the European species of the genus *Poa* have in the past received considerable attention from cytologists, the native North American species have been almost entirely neglected. Chromosome numbers of four species indigenous to this country are herewith reported for the first time.

Poa Wolfii Scribn. (Gray Summit, Missouri). Ohio to Minnesota and Missouri. 2n = 28. Figure 1.

Poa arachnifera Torr. (College Station, Texas). Southern Kansas to Texas and Arkansas; introduced eastward into South Carolina and Florida; Idaho. 2n = 42. Figure 2.

Poa cuspidata Nutt. (Vanceburg, Kentucky). New Jersey to Ohio, south to Georgia and eastern Tennessee. 2n = 28. Figure 3.

Poa sylvestris A. Gray. (Gray Summit, Missouri). New York to Wisconsin, south to Florida and Texas. 2n = 28. Figure 4.

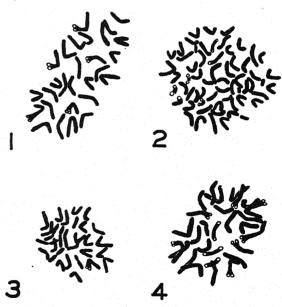

Fig. 1-4. Chromosome complements of four North American species of *Poa*. Metaphase plate, × approx. 2400.—Fig. 1. *Poa Wolfii* Scribn. 2n = 28.—Fig. 2. *P. arachnifera* Torr. 2n = 42.—Fig. 3. *P. cuspidata* Nutt. 2n = 28.—Fig. 4. *P. sylvestris* A. Gray. 2n = 28.

POA PRATENSIS.—History.—A complete taxonomic history of Poa pratensis is given in the recent work of Mecenović (1939). However, the more important treatments which have appeared since 1811

are presented in table 1 and clearly indicate the difference in opinion regarding the taxonomy of the species.

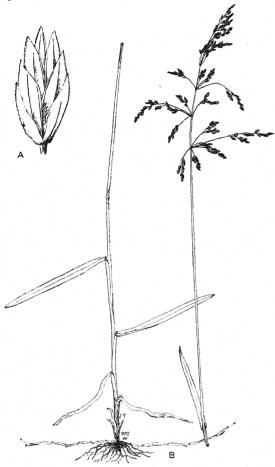

Fig. 5. Composite drawing of *P. pratensis* L. depicting a Series I plant. (A) Spikelet (×8.4). (B) Habit (×.42).

Table 1. Summary of taxonomic treatments of Poa pratensis indicating the degree to which the species has been segregated by various investigators.

Jansen and Wachter (1936)	20

Morphological variation within the species.— Morphologically Poa pratensis can roughly be divided into two groups, for convenience referred to here as Series I and II. The first includes most cultivated forms of the species and perhaps some individuals from endemic populations. They are characterized by narrow leaves, averaging 1.5–2 mm. in width, small spikelets, usually three florets per spikelet, coarse, stiff, or wiry roots, and a small number of rhizomes. The second series presents a very different picture morphologically. The leaves are much wider, averaging 3.5–5 mm., and shorter than those of the previous group. The spikelets are larger and the number of florets in each spikelet tend to be greater (4 to 5) than in Series I. Rhizomes are numerous and are longer than in the first named group.

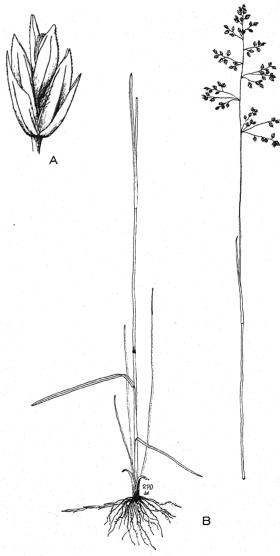

Fig. 6. Composite drawing of *P. pratensis* L. depicting a Series II plant. (A) Spikelet (×6). (B) Habit (×0.3).

The growth of these two series of forms shows striking differences. Series I, when studied in a given area of sod, presents a large number of individual plants growing close together and forming a tightly compacted mass. During fall or winter, few, if any, new rhizomes are developed. Growth is severely checked by even moderate cold, and successful transplanting can be accomplished only under the best possible environmental conditions.

A study of Series II, in a given area of sod, reveals fewer plants. All the individuals, however, are quite vigorous and are spread out so as to cover a larger area than do those of Series I. Numerous actively growing rhizomes are present in fall and winter. Growth is checked only by extreme cold, and the plants can be successfully transplanted even under the most adverse conditions. As was stated above, individuals of *Poa pratensis* can roughly be classified as belonging to one of these groups, but if a large number of plants are examined critically, their division into two groups is very difficult. Studies involving large populations show many individuals which can be classified only as intermediates between the two extremes mentioned. Although it is

difficult to build a series of forms ranging from one extreme to the other, this can be done to some extent. It is true that at least three characters remain more or less constant throughout all forms of the species. These are the presence of a web at the base of the lemma, silky pubescence on the lower half of the marginal nerves, and glabrous intermediate nerves. Neither is the shape of the ligule very variable, but the diversity in other important characters is such as to convince one that it cannot be due to chance alone.

Figures 5 and 6 show in a more exact manner the type of variation under discussion.

Cytology.—The cytological literature of Poa pratensis shows a wide variation in the chromosome numbers reported. The species possesses a basic chromosome number of seven and is highly polyploid. Diploid individuals have not as yet been found. Reported numbers range from tetraploids to

Table 2. Summary of chromosome numbers previously reported for Poa pratensis. Descriptions of plants were taken from publications in which the numbers were reported.

thirteen-ploids, including varying degrees of aneuploidy.

Stählin (1929) found the somatic chromosome number of P. pratensis to be 56. Avdulow (1931) reported the occurrence of 2n numbers of 28, 56, and 70. Nakajima (1933) lists 70 as the 2n number for P. pratensis. The same year Müntzing, working with Swedish material, gave for eight collections the following somatic numbers: 68,  $\pm$  64,  $\pm$  85,  $\pm$  75, 81–82, and 49. Seven of the eight biotypes in-

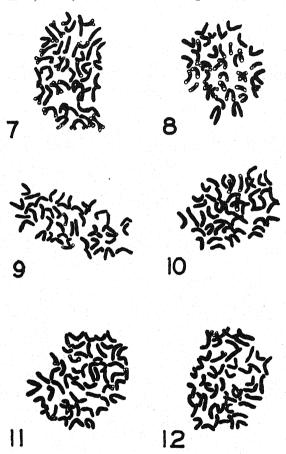

Fig. 7-12. Chromosome complements of six biotypes of  $P.\ pratensis\ L.$  Metaphase plates,  $\times$  approx. 2400.—Fig. 7. Nursery E. D. 2n=45.—Fig. 8. Nursery S. E. B.  $2n=41\pm 1$ .—Fig. 9. Nursery N. B. 2n=45.—Fig. 10. Nursery E. A.  $2n=50\pm 1$ .—Fig. 11. Cabin C. 2n=56.—Fig. 12. Nursery N. A. 2n=49.

vestigated by Müntzing are shown to have aneuploid numbers. In a study of seed formation in P. pratensis, Åkerberg (1936) lists chromosome numbers ranging from 47 to 95. Armstrong (1937) determined the chromosome number of nineteen plants from nine sources, including commercial seed and supposedly indigenous sod. Nine of his plants are shown to have euploid and ten to have aneuploid numbers—namely, 50,  $70\pm1$ , 72, 54,  $86\pm1$ ,  $87\pm1$ ,  $84\pm1$ ,  $69\pm1$ , 70, 64, 56, and 65. In all the works cited above (excepting Armstrong) little

if any mention is made of the morphological characters of the plants examined. This is unfortunate, since chromosome numbers without accompanying morphological data are of little significance to either the systematist or the cytologist.

Chromosome numbers as reported in previous cytological works are summarized in table 2.

Observations.—The twelve collections of pratensis studied, with their somatic chromosome numbers and outstanding morphological characters, are listed in table 3. The localities from which the material has been collected are used as names merely to distinguish the plants.

Following is a description of the plants listed in table 3.

Cabin C. An octoploid: Leaves averaging 2-2.5 mm. in width. Spikelets containing three small florets. Rhizomes few. 2n = 56. Series I.

Cabin G. A plant hardly distinguishable from Cabin C, except for its chromosome number.  $2n = 56 \pm 1$ . Series I.

Nursery E. C. A form with narrow leaves which average 2 mm. in width. Leaves somewhat more involute than those of Cabin C. or G. Rhizomes few. 2n = 56. Series I.

Nursery E. A. An intermediate between Series I and II.  $2n = 50 \pm 1$ .

Nursery N. A. 2n = 49. Series I.

Nursery E. D. A wide-leaved an euploid with numerous rhizomes. Extremely vigorous. Leaves lacking the dark green color of most forms. 2n = 45. Series II.

Alleghany. Intermediate between Series I and II. Leaves averaging 2-2.75 mm. in width, 2n = 56.

Nursery N. B. 2n = 45. Series II.

Nursery S. E. B. A wide-leaved type, leaves averaging 3.5 to 4 mm. in width. Rhizomes numerous.  $2n=41\pm1$ . Series II.

Nursery S. X. The extreme in this direction. Leaves averaging 4 mm. in width. Single plant may possess as many as sixty rhizomes. 2n = 42. Series II.

Helms. Leaves narrow, averaging 1.5 mm. in width. Spikelets containing three florets. Rhizomes few. 2n = 64. Series I.

Schoolcraft. 2n = 56. Series I.

<sup>\*</sup> Missouri Botanical Garden Arboretum, Gray Summit, Missouri

b Missouri Botanical Garden, St. Louis, Missouri.

It will be noted that five of the twelve collections reported are aneuploid, a fact not in absolute agreement with previous cytological work. Müntzing, for instance, found aneuploid numbers in seven of the eight biotypes investigated by him. This variation in the extent of occurrence of aneuploid forms in different parts of the world may in some degree account for the diversity of opinion concerning the extent of apomixis within the species.

Müntzing's evidence for the occurrence of apomixis in this species is based on the cytological and morphological constancy of aneuploid forms. Although these facts are suggestive of apomixis, the evidence is of course indirect. If, however, the percentage of aneuploidy present is used as a basis upon which to work, the present investigation would indicate that apomixis in *Poa pratensis* may not be as common a phenomenon as is often supposed. The problem can be solved satisfactorily only through critical progeny analyses and embryological studies.

It has been found from the plants examined and from the cytological literature that octoploidy is more frequent than any other degree of polyploidy (fig. 13). This may be at least partially explained by the occurrence of octoploidy in most cultivated forms. Degrees of polploidy beyond thirteen-ploids have not been observed in this study, nor have the lower polyploid forms (tetraploids and pentaploids) been found. The lowest 2n number encountered is a near hexaploid,  $41 \pm 1$ , while the highest number is 64.

Although the chromosome morphology of these forms has not been studied intensively, there is considerable variation in chromosome length. Attachment constrictions are usually median or sub-median, regardless of the length of the chromosome involved (fig. 7–12). No satellited chromosomes have been found.

Correlation of cytology and morphology.-Leaves, spikelets, and rhizomes all possess the range of variability characteristic of the species, and since leaves and rhizomes can be observed throughout the year, they have been selected as the principal morphological tools with which to work. The leaves of mature plants of pratensis vary in width from 1.5 to 4.5 mm. Although length of leaves has not been as carefully studied as has leaf width, the wide leaves are usually shorter than the narrow ones. Inflorescences are divided easily into two groups: the first possesses a relatively narrow panicle, small spikelets, each spikelet containing 2 to 3 (usually 3) florets; the second type characterized by a wide, open panicle with large spikelets, each spikelet containing 4 to 6 florets.

Rhizomes within the group show a difference only in number and length, but it is not due to environment. Plants selected from various localities and grown under identical<sup>2</sup> conditions vary extremely in the number of rhizomes produced in a one-year period. Some plants under ordinary conditions will

<sup>2</sup> With the exception of any soil heterogeneity which might be present within a given plot.

produce in one year as many as sixty new rhizomes, others grown in the same plot will produce only ten or twelve. All plants, of course, cannot be separated into groups producing approximately sixty or approximately ten new rhizomes in one year. Numerous intermediate forms are found. Variation in a group of plants is in itself of little significance, but the manner of variation is quite important, and it is that point which should be emphasized in this particular case.

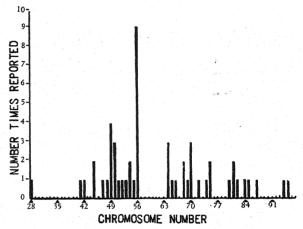

Fig. 13. Distribution of chromosome numbers in P. pratensis L.

Variation in *P. pratensis* is not at random, but there is a strong tendency for morphological characters to remain together in groups. For example, one finds in combination with wide leaves wide panicle, large spikelets, tendency toward an increased number of florets in each spikelet, and long and numerous rhizomes. The opposite characters tend to be carried in combination with narrow leaves. In a study of herbarium specimens composed of plants representing the entire range of *P. pratensis* in the United States, there was found to be a significant correlation (fig. 14) between leaf-width and number of florets in each spikelet. In this study the leaf-width and floret-number for each plant represent an average of at least six counts.

Excellent facilities for a study of the relationship between leaf-width and rhizome-number were offered by plants growing in the nursery, Rhizome counts and measurements of leaf-width were made on these plants in the spring of 1939. Due to the fact that in this climate P. pratensis rhizomes develop almost entirely during September to November, it was possible at that time to determine with fair accuracy the number of new rhizomes developed within one year. Although the small number of plants used here reduces the significance of the correlation, there still is shown to be a definite relationship (fig. 15) between leaf-width and number of rhizomes present. This, in addition to the evidence mentioned earlier, seems to be a sufficient basis for establishing the fact that characters, although variable, do not segregate at random but remain together in groups. One may also assume that this variation is regulated by two distinct genomes which, for convenience, may be designated as genome A and genome B. The action of these will be discussed later.

An explanation of the above may be found in the cytology of the plants involved, which is no less variable or complex than is the morphology. At least

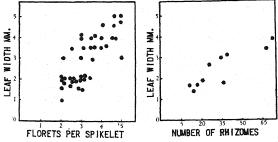

Fig. 14 (left). Analysis of forty plants showing the relationship between leaf-width and number of florets per spikelet.

Fig. 15 (right). Analysis of ten plants showing the relationship between leaf-width and rhizome number.

twenty-eight chromosome numbers have been reported for the species, a range of counts fairly high for a group of plants possessing a basic chromosome number. The cytological evidence at hand suggests the operation of two processes which, when working in combination, may account for the extreme variation in this plant. These are (1) polyploidy and (2) apomixis.

Since polyploidy tends to increase the potential range of species variation, it is logical to expect a wider range of variability in P. pratensis, which has a polyploid range of 4n to 13n, than in a species of less cytological complexity. The type of polyploidy (allo- or autopolyploidy) operating within P. pratensis has not as yet been determined, and the direct evidence will have to come from a study of chromosome association at meiosis. On the other hand, critical observation of the variants enables one to form an hypothesis regarding the type of polyploidy involved. Were only autopolyploidy present, one would expect to find changes in degree only. Since there has been shown in pratensis changes not only in degree but also in form, it seems justifiable to suggest the presence of at least some allopolyploidy.

Another point which supports to some extent the theory for an alloploid origin of *P. pratensis* is the presence of apomixis, a phenomenon often associated with hybridization. It seems probable that polyploidy, whether it be allopolyploidy, autopolyploidy, or a combination of the two, is the most important factor in the production of variable types within the species. On the other hand, apomixis certainly has made possible the persistence of many forms which, if sexual, would have been partially or entirely eliminated due to difficulties of chromosome pairing at meiosis (Darlington, 1937, Ch. IV). Contributions to our knowledge of apomixis and the development of the caryopsis in *Poa* have been made

by Andersen (1927), Nishimura (1922), Müntzing (1933), Åkerberg (1936), and Kiellander (1937). Despite these works and other papers which have appeared on the subject, the extent of apomixis in *P. pratensis* is still an unsettled question. At present the most conclusive evidence for this phenomenon is the fact that a large number of aneuploid forms exist in any population. If these forms are cytologically and morphologically constant, as has been suggested by other workers, then the evidence, although still not direct, is somewhat more conclusive.

Before offering a specific cytological explanation of the variation in this plant it is necessary to describe any association which may exist between cytology and morphology. Briefly it is as follows. Plants with wide leaves, large spikelets, and many rhizomes are relatively low polyploids, Plants with narrow leaves, small spikelets, and few rhizomes, on the other hand, are high polyploids. Those plants whose morphological characters tend to place them as intermediates between Series I and Series II have chromosome numbers intermediate between high and low polyploids. In *P. pratensis* the optimum for chromosome increase beyond which there is a decided decline in vigor is near the hexaploid condition.

Using the evidence cited above, the following hypothesis might be offered as an explanation of the processes continually at work within the germ-plasm and which are in turn directly responsible for the extreme variation as expressed in the phenotype. It has been previously mentioned that the germ-plasm of pratensis is apparently composed of two genomes which, as expressed in the morphology of the plant, are found to exert entirely different influences. For instance, one genome (A) may carry characters for wide leaves, large spikelets, and long rhizomes; the other (B) may be capable of producing narrow

leaves, small spikelets, and short rhizomes. It is logical to assume that the morphology of any given plant is determined by the balance between the two kinds of genomes composing its germ-plasm. A plant of the constitution AAAA/BBBB would be expected to be a more extreme example in the direction of Series I than a plant whose germ-plasm contained AAAA/BB. In this connection it may be expedient to list the hypothetical genome balance of all the plants included in table 3.

It is shown in the list above, as well as in figure 13, that 56 is the modal chromosome number for the species. It seems most likely that this number has arisen from a cross between two tetraploids of the constitution AAA'A' × BBB'B'. If this is true. one can then assume that the various other forms within the species, with chromosome numbers other than 56, have arisen by a loss or duplication of one or more chromosome sets. Thus 49, the number of next greatest frequency, is likely the result of a loss of one chromosome set, and since for the most part those plants possessing 49 chromosomes are members of Series II, the lost set may be assumed to have belonged to genome B. The number 64 has probably arisen from 56 by a duplication of one genome plus one chromosome. In this instance the extra genome is apparently a member of A, since plants with 64 chromosomes belong to Series I.

Until further study yields more direct evidence this can of course be accepted only as a working hypothesis. The germ-plasm of P. pratensis may contain three or even more genomes, but the evidence at hand does not suggest the presence of more than

In view of the above cytological and genetic evidence the presence of extreme variation in this plant is not surprising. One would expect the tetraploid, hexaploid, octoploid, and decaploid forms to be more or less regular cytologically and thus capable of reproducing themselves sexually. This complex alone would result in no small amount of intra-specific variability. Furthermore, when to this sexual complex are added the various aneuploid forms which are being reproduced asexually through apomixis, it is understood easily why P. pratensis presents such a variety of diverse forms.

According to these observations, the segregation of species, subspecies, varieties, forms, etc., from P. pratensis, a practice well known to European botanists, hardly seems justifiable. It is true that without much difficulty forms which are morphologically different can be found, but it is difficult to understand how such groups can be segregated either specifically or varietally without overlooking intentionally the various intermediate forms.

### SUMMARY

Previously unreported chromosome numbers have been determined for four species of the genus Poa.

A high degree of non-random intra-specific variation is present in Poa pratensis. This is due to polyploidy and aneuploidy.

Chromosome numbers ranging from  $\pm$  41 to 64 are reported for twelve biotypes of pratensis.

The probable occurrence of apomixis and the presence of "group segregation" form a basis for the suggestion of an alloploid origin for the species. An hypothesis, based on the genome balance

within the germ-plasm, is offered as an explanation of the morphological variation within the species.

# RESPIRATION AND FERMENTATION IN THE CARROT, DAUCUS CAROTA I. RESPIRATION <sup>1</sup>

# Paul B. Marsh and David R. Goddard

ALTHOUGH THERE has been a great deal of research in recent years dealing with the nature of respiration and fermentation in yeast and in animal tissues, higher plants have not been intensively investigated in this regard. It has been the purpose of this study to investigate the nature of respiration and fermentation in the carrot, Daucus carota, and to extend our knowledge concerning the relationship between these two processes. Part I is a report of the experiments on respiration, while Part II, to be published shortly, presents the experiments on fermentation and its relationship to respiration.

Three distinct oxidases involved in plant respiration are now known-cytochrome oxidase, catechol oxidase, and a group of oxidases known as the flavine or vellow enzymes. Cytochrome oxidase (Keilin, 1929) also known as indophenol oxidase or phaeohemin oxidase (Warburg, 1927), is found in veast and is widely distributed in the animal kingdom. It is inactivated by cyanide, azide, and carbon monoxide, the carbon monoxide inhibition being light reversible. Catechol oxidase (Batellei and Stern, 1912; Keilin and Mann, 1938; Kubowitz, 1937), occuring primarily in plants, is inactivated by the same three poisons, but the carbon monoxide inactivation is not light reversible. The flavine enzymes (Theorell, 1937), the first of which was isolated from yeast only seven years ago (Warburg and Christian, 1932), are cyanide-insensitive oxidases, whose prosthetic group is a phosphate ester of vitamin B2 (riboflavine).

In this paper we present evidence for the operation of two different oxidases in the carrot plant. One of these is quite similar to or identical with the cytochrome oxidase and accounts for the major part of the respiration of the carrot root and young leaves. The other, insensitive to poisoning by cyanide, azide, and carbon monoxide, accounts for a fraction of the respiration of roots and young leaves and the entire respiration of mature leaves.

Materials and methods.—Warburg (1928) clearly stated the simple assumption involved in the use of reversible enzyme poisons such as cyanide and carbon monoxide in the study of cell metabolism. A poison of known chemical behavior is assumed to react inside the intact cell with enzymes which contain chemical groups of the same type with which this poison reacts in vitro. Removing the poison or otherwise breaking up the enzyme-poison compound allows the metabolism to return to its original unpoisoned state. By this method we may study respiration and fermentation in the cell under relatively normal conditions.

Carrots of the horticultural variety Nantes Coreless, grown in the university greenhouse, were used for these experiments except where otherwise designated. Some preliminary experiments were made

<sup>1</sup> Received for publication June 30, 1939.

on carrots of unknown variety from commercial sources; these carrots are designated "B." Experiments in the fall of 1938 were made on carrots of the variety Nantes Coreless bought from a farmer near Rochester, stored in sand in a cool place and used as needed; these carrots are designated "F." No qualitative differences among these carrots from different sources have been noted in the experiments to be reported, and all direct quantitative comparisons are between carrots from a single source.

Plugs 6 mm. in diameter were cut from the carrot roots with a cork borer and the cortex from the plugs sliced with a razor into sections approximately 0.5 mm. thick. Oxygen consumption and carbon dioxide production of 400–500 mg. wet weight of these slices suspended in 2 ml. of M/60 Sorensen's phosphate buffer of pH 5.9 were measured in a Fenn (1928) microrespirometer at a temperature of  $22 \pm 0.005$ °C.

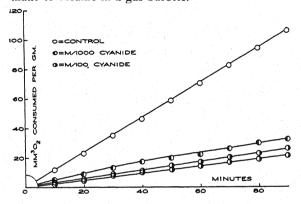

The apparatus used had a capillary volume of 3.0 mm.3 per cm. of length, giving a sensitivity which varied for individual manometers of 1.0 cm. deflection equal to 5.5 to 6.0 mm.3 Readings were taken at five- or ten-minute intervals and the oxygen consumption calculated by multiplying the observed movement of the bubble times the oxygen constant for the particular vessel. The rate of oxygen consumption was usually fairly constant with time, as may be seen, for instance, from the control vessel values in figure 1. Although the rate of oxygen consumption per gram fresh weight per hour varied considerably from one batch of carrots to another, the agreement between samples used in any one experiment was fairly satisfactory. The percentage deviation from the mean of two duplicate controls for a 60-minute interval was calculated for each of ten experiments; the average percentage deviation from the mean was 4.3 per cent.

Respiration of leaf tissue was measured by floating 100 mg. samples on phosphate buffer. All respiratory measurements on leaves were made in a photographic dark room, using a very weak light only during the actual reading of the apparatus. Since large respiratory differences exist between different samples of carrot leaves, the oxygen consumption of unpoisoned leaves was first determined, and then the poisons added, and a second determination made on the same tissue.

The rate of oxygen diffusion into the tissue from air did not limit the rate of root respiration. At 2.5 per cent oxygen the rate of respiration was always below the rate in air, but at 5 per cent there was sometimes a decrease and at other times not. Values for mm. <sup>3</sup>/gm./hr. in air of 93.2, 91.0, 97.8, 76.0, 76.0 were obtained as against corresponding values in the same five experiments of 88.2, 57.0, 75.2, 84.0, and 53.0, respectively, for 5 per cent 0<sub>2</sub>, 95

per cent  $N_2$ . Raising the oxygen percentage to 100 per cent resulted in a slight, but probably not significant, increase in oxygen consumption. Four hundred mg. of roots consumed 49.6 mm.<sup>3</sup> of  $0_2$  in 70 minutes in air and 54.2 mm.<sup>3</sup> in a subsequent equal period of time in pure  $0_2$ .

Acid or alkaline poisons were made up at several times the desired final concentration, neutralized to pH of 5.7–6.0 as determined at a quinhydrone electrode, then diluted with phosphate buffer of pH 5.9 to give the desired concentration. The acidity of the poison-containing suspending media was rechecked as a routine matter after each experiment. In poisoning with cyanide, KOH–KCN mixtures were used in the inset (Krebs, 1935). CO was made by dehydrating formic acid with hot sulfuric acid, was passed through sodium hydroxide solution to remove any traces of formic acid and the gas mixtures made to volume in a gas burette.

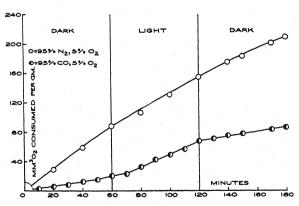

Fig. 1 (above). Inhibition of carrot root respiration by cyanide.

Fig. 2 (below). Light reversal of carbon monoxide inhibition of carrot root respiration.

EXPERIMENTAL RESULTS.—Reversible inhibition of root respiration by cyanide.—The respiration of carrot roots, like that of yeast and muscle, is reversibly inhibited by low concentrations of cyanide, as may be seen from table 1 and figure 1. The respiratory rate of cyanide-poisoned carrots, after an initial period of falling rate, was practically constant with time (see fig. 1). It will be noticed from the table that even with the highest concentrations

of cyanide there remained a small residual respiration. The reversible nature of the inhibition was established by removing the carrots from the cyanide media, washing, and replacing the KOH-KCN inset mixture with KOH. Values of oxygen consumption in cyanide in mm. <sup>3</sup>/gm./hr. of 21.5, 19.8, 23.6, and 27.7 rose to 60.5, 42.1, 67.5, and 95.0, respectively, after washing.

<sup>b</sup> Source B.

Light reversible inhibition of root respiration by carbon monoxide.—It was found that carrot root respiration is inhibited by carbon monoxide and that this inhibition may be reversed by light. Light from a bank of Mazda lamps, one 100-watt lamp about ten cm. below each experimental vessel, caused this reversal in each of the ten determinations. A graph of a characteristic experiment is shown in figure 2, while table 2 presents the results of three other experiments.

Warburg (1927) showed that with substrate saturation the ratio of residual respiration/respiration

Table 2. Inhibition of root respiration by carbon monoxide and light reversal of this inhibition. Poisoned = 95 per cent CO, 5 per cent  $0_2$ ; Control = 95 per cent  $N_2$ , 5 per cent  $0_2$ .

inhibited is proportional to  $pO_2/pCO$  and also proportional to a constant, K, expressing the relative affinity of the enzyme for  $O_2$  and CO. Using the equation:  $K = \text{residual respiration pCO/respiration inhibited pO}_2$ , Warburg obtained values for K of from 4.3 to 13 in experiments with yeast. We obtained values for K from our experiments which are quite comparable to Warburg's figures (see table 3). (Warburg points out that although haemoglobin also forms a compound with carbon monoxide, its K is about 0.01.)

Table 3. Relative affinity of the enzyme for oxygen and for carbon monoxide. Sixty minutes in all cases. Poisoned = 95 per cent CO, 5 per cent  $\theta_2$ . Control = 95 per cent  $N_2$ , 5 per cent  $\theta_2$ .

	24.3	(63.4)	61.6	11.8	

\* The parentheses indicate the use of a single control vessel determination to calculate percentages of inhibition of more than one poisoned sample in the same experiment.

Kempner (1936) has observed light-reversible CO inhibition of respiration in several plant tistues—plum and daffodil pistils and stamens, pine needles, leaves of tobacco, plum and oleander.

Reversible inhibition of root respiration by azide.

—Carrot root respiration, like that of yeast and heart muscle, is inhibited by low concentrations of sodium azide (NaN<sub>3</sub>). However, the percentage inhibition does not increase markedly with increasing acidity of the suspending medium as is the case with yeast and heart muscle (Keilin, 1936). A sixtyminute experiment gave the results shown in table 4.

Table 4. Inhibition of root respiration by azide at different acidities.

- Hamana	$0_2$ in mm.3/gm. in 60 min.

	5.1	80.2	19.6	75.6	
	5.7	68.4	19.8	71.0	

The sodium azide inhibition was reversed by washing the carrot slices thoroughly in distilled water. A determination of the normal rate of respiration of three unpoisoned samples was followed by a determination of the respiratory rate in M/1,000 sodium azide; finally these samples were washed in water and the three individual respiratory rates de-

termined again. Results of this experiment are presented in table 5.

Table 5. Reversal of NaN<sub>3</sub> inhibition of respiration. Total time for each determination: 30 minutes. Readings at 5-minute intervals and rates constant. NaN<sub>3</sub> at 10-3 M.

Dye reactions.—Since the respiratory inhibitions of carrot roots showed a general similarity to those of yeast, experiments were undertaken on the indophenol oxidase reaction. Yeast and most animal tissues markedly catalyze the oxidation of di-methyl p-phenylene diamine and alpha-naphthol (the Nadi reagent) to indophenol blue by molecular oxygen. This reaction in yeast is completely abolished on killing the yeast by boiling and is sensitive to the same poisons (HCN, H2S, CO with light reversal) as normal yeast metabolism and the oxidation of cytochrome in intact yeast (Keilin, 1929; Meldrum, 1934). The carrot roots gave a weak but positive reaction with the Nadi reagent and unexpectedly gave a positive reaction even after boiling the tissues. This observation led us to measure the oxygen consumption of dead carrots plus dyes.

Table 6. A dye oxidation catalyzed by dead carrots. Source: F.

mm.3 $0_2$ consumed/hr./350 mgs. tissue		
Live carrots:		
Control	26.8; 26.6	
Plus P.P.D.a	47.9; 54.3	
Plus catechol	31.8; 29.3	
Plus P.P.D. and catechol	95.6; 111.6	
Boiled carrots:		
Control	0.0	
Plus P.P.D	20.3	
Plus P.P.D. and catechol	73.5	
Plus P.P.D.; catechol, and M/1,000 HCN	10.3	
Dye controls:		
Catechol	0.0	
P.P.D	17.7	
P.P.D. and catechol	17.1	

\*P.P.D. = p-phenylene diamine; 10 mg. of P.P.D. or catechol where mentioned.

Table 6 shows that carrots which had been killed by boiling and gave no measurable oxygen consumption failed to catalyze the oxidation of p-phenylene diamine but did, however, give a marked cyanidesensitive catalysis of oxygen uptake in the presence of a mixture of p-phenylene diamine and catechol. (A slight temporary catalysis was observed in the presence of catechol alone.) A graph showing catalysis of the oxidation of this mixture by dead as well as by living roots is presented in figure 3. No control with p-phenylene diamine + catechol in the absence of carrots was run in the experiment graphed, but reference to table 6 shows that the rate of auto-oxidation is fairly low, less than 20 per cent of the rate with dead carrots as graphed in figure 3.

In the past, investigators of the qualitative nature of plant respiration have commonly depended on the use of color reactions with oxidizable artificial dye substances rather than on determinations of oxygen consumption. Apparently in some cases proper attention has not been paid to the importance of pH, the possibility of negative tests due to reduction as well as oxidation of the dye by the tissue, and the possibility of catalysis of dye oxidation by thermostable cell components not concerned in respiration.

Bhagvat and Richter (1938) report fairly general catalysis of oxidation of various phenolic compounds in the presence of small amounts of metallic ions; copper, iron, nickel, cobalt, and manganese. They have also demonstrated pseudophenolase activity—that is, they have isolated from the crab, Cancer Pagurus, a hemocyanin showing very definite phenolase activity, but still activity of a very much lower order of magnitude than that of true phenolases, such as Keilin and Mann's (1938) catechol oxidase. Our results with dye reactions of dead carrots are a further admonition to use care in the interpretation of this type of test.

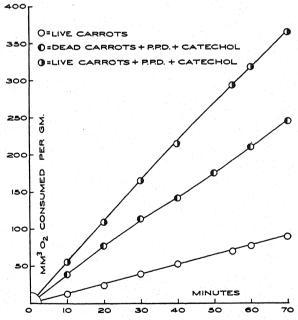

Fig. 3. Catalysis by dead carrots of the oxidation of p-phenylene diamine + catechol by molecular oxygen.

The shift in oxidase on growth of carrot leaves.—When CO, HCN, and NaN<sub>3</sub> were used as respiratory poisons on immature leaves (inner leaves of the rosette, 3 cm. or less in length), inhibition of respiration was found with all three poisons, as may be seen from table 7. However, the respiration of ma-

ture leaves (outer leaves of the rosette, at least 25 cm. long) was not inhibited by any of these poisons, see table 8. The failure of these poisons to inhibit the respiration of mature leaves cannot be due to failure to penetrate the cells for the following reasons: (1) leaf tissue that is readily permeable to the gases CO<sub>2</sub> and O<sub>2</sub> can hardly be impermeable to the gas CO; (2) cyanide occasionally caused a respiratory stimulation; (3) no respiratory inhibition was found even when the leaves had been allowed to stand with their petioles in NaN<sub>3</sub> for 16 hours.

From these experiments we may conclude that a qualitative change in the respiratory mechanism occurs on maturation of the carrot leaves. It may be noted that on a wet weight basis, young carrot leaves respire more than twice as fast as mature leaves and almost ten times as fast as root tissue.

The fact that the normal respiratory rate of mature leaves was of the same order of magnitude as the residual rate of poisoned young leaves (see table

Table 9. Summary of respiratory rates with and without cyanide or azide for roots, mature leaves, and young leaves.

mm. $^3$ $^02/\mathrm{gm./hr.}$

<sup>&</sup>lt;sup>a</sup> The figures in parentheses indicate the number of determinations used in calculating the average.

9) suggested a speculation. It may be that two qualitatively different oxidase systems are operative in the young leaf, one of which, the cyanide-azide-CO sensitive one, is lost during development while the basic insensitive system persists throughout development. The simultaneous operation of two distinct oxidases has recently been very beautifully demonstrated by Stannard (1939); by use of sodium azide Stannard has separated the normal resting respiration of frog muscle from the extra respiration which is superimposed upon this normal respiration when the muscle is stimulated by caffeine or by electrically or chemically induced contracture.

Although catechol oxidase, an enzyme inactivated by cyanide, azide, and CO (Keilin and Mann, 1938), has long been considered a common plant oxidase, it is interesting to note that the respiration of the mature leaves of both higher plants recently investigated in this laboratory, wheat (Allen and Goddard, 1938) and carrots, has not been inhibited by these poisons. Further, the light reversal of the carbon monoxide inactivation of the primary oxidase of the carrot root shows that this respiration is not due to catechol oxidase.

### SUMMARY

The respiration of carrot root is reversibly inhibited by low concentrations of cyanide and azide. Cyanide at a concentration of  $10^{-2}$  M, however, does not completely inhibit the root respiration.

The respiration of carrot root is also inhibited by carbon monoxide; this inhibition may be reversed by light.

The enzyme which combines with carbon monoxide has an affinity for oxygen in the range of 9 to 13 times its affinity for carbon monoxide. This has been calculated according to Warburg's equation and our values agree well with Warburg's values for yeast.

These results suggest the operation of an enzyme similar to or identical with the cytochrome oxidase (indophenol oxidase) of yeast.

The light reversal of carbon monoxide inhibition of respiration indicates that catechol oxidase, long held to be the common respiratory enzyme of higher plants, is not the enzyme involved in carrot root respiration.

Carrot roots killed by boiling, though they do not consume oxygen, still give a positive Nadi reaction; they also catalyze (as determined by O<sub>2</sub> consumption) the oxidation of a mixture of p-phenylene-diamine and catechol.

The respiration of immature carrot leaves is similar to that of roots in being inhibited by NaN<sub>3</sub>, HCN, and CO, but when the leaves become mature, the respiration is not inhibited by any of these poisons.

### THE SELENIFEROUS ASTRAGALUS OSTERHOUTII JONES 1

### O. A. Beath

CONSIDERABLE STUDY has been directed during the past few years to species in the Lonchocarpi group of Astragali as possible carriers of selenium. The reason given for anticipating this characteristic development was based upon the analogy of the Lonchocarpi and Bisulcati groups. According to Jones (1923) "This group (Lonchocarpi) is nearest related to the Bisulcati because of its compressed pod inclined to be bisulcate, one-celled, stipitate and opening only along the ventral suture but in other features it approaches the Homalobi." He further states: "The Lonchocarpi group doubtless has a relationship, though a loose one, with the racemosus part of the Galegiformes being a little more aberrant than A. drummondii. It is, like A. racemosus, a group of the alkaline plains."

The seleniferous character of all the species of the Bisulcati group and A. racemosus in the Galegiformes has been quite definitely established (Beath et al., 1939a, 1939b). In the Lonchocarpi group special consideration has been given to two valid species—viz., A. lonchocarpus Torr. and A. osterhoutii Jones. The former occurs (Jones, 1923) widely distributed from Pioche, Nevada, northward to Ferguson Spring near Ibapah, Utah, eastward from Pioche north of the Grand Canyon along the Virgin (north of Cedar City) and the Kanab region, throughout the Navajo Basin drainage eastward through Durango and the Little Colorado, to the Rio Grande, thence northward to Pueblo and Canyon City. A. osterhoutii has not been reported to occur outside of Grand County, Colorado.

Astragalus lonchocarpus has not been found to absorb selenium in toxic amounts. Representative samples have been obtained from Colorado, New Mexico, Utah, and Idaho. Field observations indicate that it is not necessarily confined to soils of a seleniferous character. A. lonchocarpus is regarded by stockmen to be a desirable range plant (Goodding, 1939). Consequently it seems quite probable that this species has no appreciable toxicity insofar as selenium involvement is concerned. On the other hand, A. osterhoutii is to be considered as a positive selenium carrier. Furthermore, its growth is associated exclusively with seleniferous shales. A representative collection was obtained July 3, 1939, six miles north of Kremmling, Colorado, on Niobrara shale. The plants at that time were in the early seed stage. The selenium value on air dried plants was found to be 2,678 parts per million. Later collections during July from the same general area north of Kremmling were submitted to selenium tests. All were definitely positive. The seleniferous character of A. osterhoutii has, therefore, been clearly established. It has also been observed that the plants, green or dry, emit the selenium odor so characteristic of many of the seleniferous Astragali (Beath et al., 1939a).

<sup>1</sup> Received for publication September 8, 1939.

In the same Kremmling area the author found other selenium-bearing Astragali, notably A. haydenianus Gray and A. pattersonii Gray. It was interesting to observe that for comparable stages of growth the A. osterhoutii was much more seleniferous than A. haydenianus or A. pattersonii under identical soil conditions.

A large collection of A. osterhoutii was made during July for animal feeding tests. A pound of air dry material (whole plant) was sufficient to produce death in a sheep within a few hours. So far as the author is aware no previous mention has been made of the toxic character of this species of Astragalus.

Beath et al. (1939a, 1939b) and Trelease (1939) have presented evidence that indicates a tendency for only certain species of Astragalus to be natural absorbers of selenium. Beath et al. (1939a, 1939b) have pointed out that exceptions occur. One of the most prominent cases involves the non-seleniferous A. drummondii Dougl. and the positive seleniferous A. racemosus Pursh. Both are classified by Jones (1923) as occurring in the Galegiformes group. No reason can be given at this time as to why this diversity of selenium absorption occurs in the Galegiformes group.

The significant point brought out in the chemical study of two valid species in the Lonchocarpi group is that one is seleniferous and the other is not. The author has not been able to obtain specimens of the other species in the Lonchocarpi group—viz., A. kaibensis Jones and A. duchesnensis Jones.

From a genetic point of view one may well raise the question as to why A. osterhoutii is consistently seleniferous and A. lonchocarpus is non-seleniferous. Is it because of a carry-over of the bisulcate influence (selenium absorption) into the A. osterhoutii that was left out of A. lonchocarpus? If not the bisulcate influence, could it be assigned to an A. racemosus trend? Or is it a dual influence? In any event it would seem to the author that this interesting diversity offers a geneticist an opportunity to investigate a problem unique in its field. If the seleniferous Astragali were scattered here and there throughout the western United States independent of any group association, it would be clearly impossible to assign any genetic basis for their selenium absorbing properties. Since preliminary data strongly indicate the possibility of a segregation, in a majority of cases, of those species that are seleniferous into definite groups, it would appear logical to conclude that a basic reason exists for such a behavior.

### SUMMARY

Astragalus osterhoutii and A. lonchocarpus are valid species belonging to the Lonchocarpi group. A. osterhoutii is confined in its growth to seleniferous soils and in addition is capable of absorbing selenium in toxic quantities. Consequently it may be

looked upon as a livestock hazard and also as a soil contaminator.

A. lonchocarpus is not confined in its growth to a seleniferous soil. Samples from a diversity of soils from four western states have been analyzed for selenium with negative or very low results. It is concluded that this species does not absorb selenium in toxic amounts even from soils known to contain appreciable amounts of soil selenium. It is regarded by stockmen to be a safe forage.

The analogy in some respects of species in the Lonchocarpi group to those in the Bisulcati and Galegiformes would suggest that a selenium requirement has been retained through the ontogeny of A. osterhoutii that is found to be lacking in A. lonchocarpus.

# CHROMOSOME NUMBERS OF CALIFORNIAN SALVIAS 1

### Wm. S. Stewart

TAXONOMIC DIFFICULTIES with the 18 Californian species of Salvia suggested that a determination of their chromosome number might be useful. The results of such determinations are reported in this

In the New World, the genus Salvia is represented chiefly by the subgenus Calosphace (Epling, 1939). This is a complex of nearly five hundred species, which are nevertheless notably uniform in floral and vegetative habit for so large a group. Within this complex approximately ninety sections or species groups have been recognized. The species which comprise each of these groups are in general similar in growth form and floral habit. This subgenus is predominantly Andean and Mexican, reaching as far west in the United States as Arizona.

In the state of California, however, is centered a group of species of Salvia, eighteen in number, which have been variously treated by systematic writers. Five of these species, S. Columbariae, Carduacea, Greatae, californica, and funerea, have always been referred to Salvia. The remainder have been considered by some authors as generically distinct and in the past have been recognized as the genus Audibertia. Of these species, one, S. apiana, has even been proposed as the type of a third genus, Ramona. The present position of writers on the Californian flora is to refer all these species to Salvia. This position has also been adopted by the most recent monographer who has referred the whole number to Audibertia as a section of Salvia.

<sup>1</sup> Received for publication June 13, 1939.

The author wishes to express his thanks and appreciation to Dr. Carl C. Epling of the University of California at Los Angeles for aid in collecting the material and for advice on the taxonomic discussion and to Dr. Th. Dobzhansky of the California Institute of Technology for consultation in making the chromosome counts.

As might be expected, this diverse taxonomic treatment reflects the fact that, unlike the species groups of Calosphace, the species groups of Audibertia are quite diverse morphologically, both with respect to growth form and floral habit. However, from a morphological standpoint alone there are valid reasons for recognizing these groups as all being similar and hence better regarded as species which are peripheral segregates of Salvia (Epling, 1938a). Moreover, certain observations suggest that the species of Audibertia may hybridize in nature when occupying the same territory. The frequency and nature of these hybrids, which appear to be sterile, as well as the nature of the variation between the species has suggested the possibility that this group as at present constituted has had its origin, at least in part, through allopolyploidy (Epling, 1938b). Eleven presumed hybrids among different Californian species of Salvia have been recorded by taxonomists (Jepson, 1923; Munz, 1935; Epling, 1938a).

Chromosome counts were made in pollen mother cells at diakinesis stage as well as in metaphase plates in transverse sections at root tips. The anthers for the pollen mother cell determinations were collected in the field and preserved either in formalin-acetic-alcohol or in a solution consisting of three parts 95 per cent alcohol and one part glacial acetic acid. No difference in effect of the two fixatives was observed.

The root tip material was obtained using transplants from the native environment to a sand culture medium. They were watered once a week with Hoagland's nutrient solution to which had been added vitamin  $B_1$ , a root growth hormone. This was added since it has been shown by Addicott (1939) that vitamin  $B_1$  is essential for meristem cell divi-

sion in roots. For the purposes of this investigation this was of course desirable. The main root stalk had generally become well covered with young rootlets about three to four weeks after the transplantation. These were removed and fixed in Navaschin's solution for further study.

The root tip sections were cut 10 micra thick and stained with Heidenhain's iron-alum-haematoxylin. The pollen mother cell smears were made according to the method of McClintock (1929), using iron-aceto-carmine.

The results of counts are summarized in table 1. Here the species are arranged according to species groups or subsections as given by Epling (1938a). The species within a subsection form natural morphological units. Camera lucida drawings of representative metaphase plates from root tip preparations are shown in figure 1. The data show that there is no clear basic number of chromosomes for species of the section Audibertia; species with haploid numbers of 8, 11, 12, 13, and 16 are encountered. In other sections of the genus Salvia a variety of chromosome numbers is likewise established. Thus Yakovleva (1933) recorded species with n = 6, 7, 8, 9, 10, 11, 12, 16, 18, and 32. Moringa, Fukushima, and Yamasaki (1929) also report n = 8 for S. nipponica var. argutidens. It thus seems impossible to speak of a single basic chromosome number either for Salvia as a whole or for the section Audibertia alone. Regarding the chromosome number for the family Labiatae, Wanscher (1934) observes that the number 8 has been found in five out of nine genera and the numbers 9 and 12 in two genera each. He concludes that probably in this family there has been development from a 4 system.

In the case of S. carduacea the haploid number of chromosomes in several pollen mother cell counts was determined as 12, whereas both Scheel (1931) and Yakovleva (1933) indicate it to be 16. This discrepancy may be due to a racial difference in the materials used. Likewise in the case of S. Columbariae none of the published chromosome numbers agree. The same explanation given for S. Carduacea may hold in this case also. In this regard it is significant that both these species have wide distributions, since they extend over a territory about a thousand miles in length. This would afford an opportunity for the formation of genetically different races. It should be remarked, however, that both species are unusually stable and present no evidence of morphological differentiation. S. Columbariae and S. Carduacea are the only annuals in the section Audibertia, and they show low chromosome numbers, n being equal to 8 and 12, respectively. Presence of lower chromosome numbers in annuals and higher numbers in perennial species of the same ge-

nus is indeed not a rare phenomenon (Müntzing, 1936).

It is interesting to note that S. spathacea is one of the most singular species of the Salvias in California and that it is also unique in its chromosome number (2n = 26).

Another point of some interest is the diploid chromosome number found in S. carnosa subsp. Gilmani. This subspecies is largely restricted to the Panamint Mountains, west of Death Valley. It was found to have a diploid compliment of 22 chromosomes in contrast to 32 chromosomes found in S. carnosa subsp. pilosa which occurs throughout the eastern part of California. From a genetic point of view this would indicate that these two "subspecies" have reached the species rank, although they are morphologically similar. Other subspecies of this species were not investigated.

It should be pointed out that the chromosome numbers reported in this paper were established from material collected at only one locality for each species. Hence, this does not preclude the possibility that other "races" of the same species may give different results. Most of the species studied have a wide distribution.

### SUMMARY

A determination of chromosome numbers in species of Californian Salvias showed that: Paralleling the morphological diversity of the group, diverse haploid chromosome numbers of 8, 11, 12, 13, and 16 are found. Within the species S. carnosa the subspecies Gilmani has a haploid number of 11, whereas the subspecies pilosa has a haploid number of 16. There was neither evidence for nor against the suggestion that the species could have arisen either as the result of hybridization alone or as allopolyploids.

# RESPONSE OF TOMATO PLANTS TO $\beta$ -NAPHTHOXYACETIC ACID <sup>1</sup>

S. C. Bausor

In a previous paper  $\beta$ -naphthoxyacetic acid was reported as a growth-substance, stimulating growth or inhibiting it, according to the concentration used, as indicated by curvatures resulting from unilateral treatment, and later inducing the formation of root-primordia (Bausor, 1939). The present paper is a further analysis of the activity of  $\beta$ -naphthoxyacetic acid.

Methods and materials.—Potted Marglobe tomato plants about eight inches high were used as experimental plants. These were treated with lanolin solutions of  $\beta$ -naphthoxyacetic acid in concentrations of 1.0, 0.1, 0.01, and 0.001 per cent. Anhydrous lanolin, employed as the solvent for the experimental material, was used pure as a control.

The 1.0 per cent solution of  $\beta$ -naphthoxyacetic acid in lanolin was made by weighing both substances (100 mg./10 g.), while the other concentrations were made by dilution (1 g. of 1 per cent plus lanolin to make 10 g. = 0.1 per cent; 1 g. of 0.1 per cent to make 10 g. = 0.01 per cent; and 1 g. of 0.01 per cent to make 10 g. = 0.001 per cent). The material was applied unilaterally, and resulting curvatures were indicated as negative when the organ bent away from the paste or positive when it bent toward the paste, as is the convention. Seventy-four plants were used in all, eight of which served as controls.

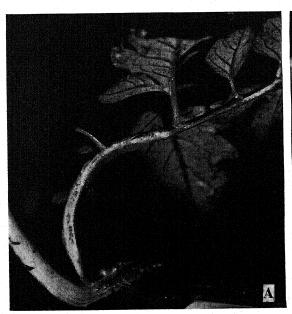

Experimental results.—Range of activity.—In an experiment designed to test the relative activity of various dilutions of  $\beta$ -naphthoxyacetic acid, four

1 Received for publication July 12, 1939.

groups of eight plants each were used, four of the plants in a group being treated on one side of the stem, the other four on the lower side of the petiole. The groups were treated, respectively, with 1.0, 0.1, 0.01, and 0.001 per cent dilutions. A fifth group of four plants served as controls and was treated with pure lanolin.

It was found that concentrations ranging from 1.0 to 0.01 per cent were physiologically effective, while a 0.001 per cent dilution was inactive. This was true whether the lanolin pastes were applied unilaterally at the apex of a stem, several internodes removed from the apex, or to the lower or upper sides of a petiole. (In a previous experiment various concentrations were applied to the upper side of the petiole, but since the lanolin gravitated to the lower side after a day or so, this method was discontinued.)

Rooting response.—About ten days after treatment an abundance of root primordia were in evidence on those plants whose stems or petioles were treated with 1.0 per cent  $\beta$ -naphthoxyacetic acid (fig. 1). Roots appeared not only on the stems or petioles where the material was smeared, but also below it, extending to the base of the stem. When the paste was applied at the apex, growth in height ceased, and eventually root primordia developed to the very apex of the plant (fig. 2). Stems treated with a 0.1 per cent paste also produced root primordia but not so abundantly as with 1.0 per cent, and only where the paste was applied to the stem. However, the plants on which petioles were treated with

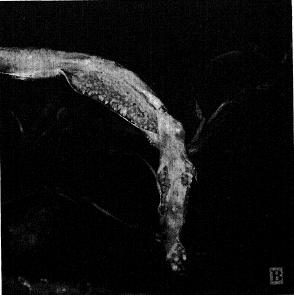

Fig. 1. Root primordia developing on stems and petioles of tomato plants after application of a 1.0 per cent lanolin solution of  $\beta$ -naphthoxyacetic acid. A. Root primordia bursting through upper side of a slightly twisted petiole. Lanolin paste on lower side is visible. B. Base of stem of plant which was treated at the apex, showing profuse and crowded root primordia breaking through the epidermis.

0.1 per cent did not develop root primordia, nor did any of the plants subjected to 0.01 per cent.

Bending responses.—Stems.—Curvatures produced by the different concentrations were rather interesting. With a 1.0 per cent paste applied to the stem, either at the apex or several internodes below, the first sign of activity in most cases was in the region of the stem below the point treated with the material. In a few cases the resulting curvature was at right angles to the paste and difficult to interpret, but in most cases it was definitely negative. This is indicative of a stimulating effect, assuming that the

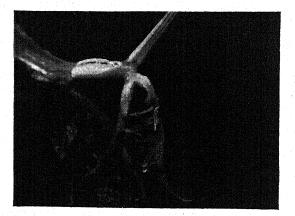

Fig. 2. Apex of tomato plant treated with 1.0 per cent  $\beta$ -naphthoxyacetic acid, showing white swollen areas of root primordia which have not yet emerged. Root primordia are developing right up to the apical meristem.

material diffused downward on the same side as that to which the paste was applied. Later the region contacted by the paste produced a strong positive curvature. The combination of the two effects resulted in a sigmoid curve. The negative curvature was so intense that the habit of the plants was changed from erect to prostrate, and when the paste was applied to the apex, the cessation of growth there made the effect permanent, except for the development of axillary buds in the lower nodes.

With a 0.1 per cent paste the bending of the stem was at first strongly negative at the place of contact with the material, sometimes followed by a slight negative curvature below. The region in direct contact subsequently developed a strong positive curvature. A 0.1 per cent paste applied to the apex likewise caused a cessation of growth and a prostrate habit, but more axillary branches developed than on plants similarly treated with 1.0 per cent  $\beta$ -naphthoxyacetic acid. With 0.01 per cent the reaction occurred only in the area treated, producing a strong negative curvature. When applied to the apex it did not stop the growth of the plant. A 0.001 per cent paste produced no curvatures.

Leaves.—A 1.0 per cent paste on the lower side of a petiole situated either at the apex of the stem or below, produced a strong negative curvature in the internode below and a strong positive curvature in the petiole. The latter was not the typical epinas-

tic response, but a more extensive growth, the petiole curving strongly wherever the paste touched it.

Petioles similarly treated with a 0.1 per cent solution curved upward at first, and the internode below it also curved negatively. The following day the curvature of the petioles was positive, but at the termination of the experiment (10 days) it was again negative.

With 0.01 per cent the petioles bowed upward negatively, but the reaction became less conspicuous as time went on, and at the close of the experiment they had resumed almost normal position. Only a slight twist indicated their previous induced excursion. The 0.001 per cent solution had no effect upon the petiole.

Rate of response.—The reaction is very rapid. In most cases a noticeable curvature, following unilateral treatment, occurs within one hour, and it becomes fairly pronounced at the end of the second hour (fig. 3, a-d).

Of the thirty-two plants experimented upon for reaction time, all but three responded within 80 minutes or less. These three reacted after two hours. In the others, curvatures were fairly pronounced at the end of two hours (fig. 3c). In a typical plant the reaction to 1.0 per cent  $\beta$ -naphthoxyacetic acid was as follows: 9:36 a.m., treated the second internode from apex; 10:40 a.m., slight negative curvature below treated area; 10:58 a.m., negative curvature greater; 11:45 a.m., very strong negative curvature; 2:57 p.m., definite positive curvature at place of contact, and below it, as before, a negative curvature; 6:18 p.m., about the same; 9:50 p.m., very strong positive curvature by tissues in contact with the paste and a very strong negative curvature below.

Although the response was somewhat different with 0.1 per cent, the time of reaction was comparable. A typical experiment follows: 9:18 a.m., treated apical internode; 10:27 a.m., slight negative curvature where paste is applied; 11:55 a.m., about the same; 1:56 p.m., strong negative curvature at place of contact, slight negative curvature below; 5:05 p.m., slight positive curvature at place of contact, strong negative curvature below.

The onset of these reactions is similar to that reported by Zimmerman and Hitchcock (1936). They noted that the response of the tomato to lanolin preparations of indolebutyric acid, indoleacetic acid, naphthaleneacetic acid, etc., occurred within one hour and that the maximum bending occurred within six to ten hours.

Discussion.—The peculiar reaction of tomato plants to unilateral treatment with 1.0 or 0.1 per cent solutions of  $\beta$ -naphthoxyacetic acid in lanolin, producing both a stimulating and an inhibiting effect, may be reasonably explained by assuming that the material becomes diluted as it diffuses into the plant and downward. This dilution probably approaches 0.01 per cent, since at this concentration a definite negative curvature is produced, and it must be greater than 0.001 per cent, at which no reaction occurs. This would account for the negative curvatures which take place below the regions smeared

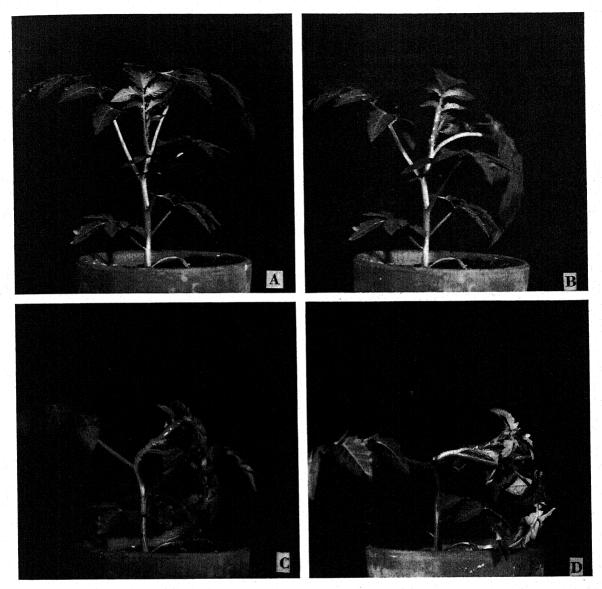

Fig. 3. Bending response and reaction time. A. Tomato plant before treatment. B. 54 minutes after a 1.0 per cent lanolin solution of  $\beta$ -naphthoxyacetic acid was applied to the lower side of the apical petiole, showing negative curvature below paste (11:01 p.m.). C. 106 minutes after treatment. Strong negative curvature below paste; slight positive curvature at region contacted by paste not obvious in photograph (11:53 p.m.). D. 154 minutes after treatment. A very strong negative curvature of stem and epinasty of leaf is in evidence below point of application, and a slight positive curvature in the treated petiole (12:41 a.m.).

with a 1.0 per cent paste, and for the negative curvatures occurring at first where the 0.1 per cent paste was applied, later followed in the same place by a reversal to a positive curvature. It seems that the  $\beta$ -naphthoxyacetic acid becomes dilute enough as it diffuses into the contacted area to produce a stimulation to the growth processes. But as more of the growth-substance enters the tissues, the original negative curvature disappears and a strong positive curvature is found in its place, indicating that growth has been inhibited on the treated side and is now slower than that of the opposite, untreated side.

The inhibition of growth in length by concentrations of 0.1 and 1.0 per cent further bears out this contention.

Zimmerman and Hitchcock (1936) reported that low concentrations of growth-substances in lanolin induced negative bending of stems and leaves, while high concentrations induced positive bending. For naphthaleneacetic acid, which is structurally similar to  $\beta$ -naphthoxyacetic acid, they found that concentrations ranging from 0.002 per cent to 1.0 per cent produced negative curvatures, and percentages of 2 or more caused positive bending.

The negative curvature which occurs at first with 1.0 and 0.1 per cent  $\beta$ -naphthoxyacetic acid places the stem out of line of the direction of the gravitational pull, but the magnitude of the positive curvature which follows indicates that the reaction is not solely, if at all, a secondary, negative, geotropic response to lateral displacement.

With a 0.01 per cent concentration, however, the negative curvature almost disappears (if the treatment is at the apex) as a result of subsequent faster growth on the lower side of the horizontally curved stem responding to a geotropic stimulus. When applied below the tip on slower growing tissues, the negative curvature does persist as a crook in the stem, the geotropic curvature occurring above it. Since it is now known that geotropic responses are influenced or caused by natural plant hormones and growth substances (Boysen Jensen, 1936; Zimmerman and Hitchcock, 1936, 1938), this secondary effect probably is due to the radial distribution of natural hormones overcoming the effect of the stimulus of the artificial growth substance.

The subsequent development of root primordia only with concentrations which inhibit growth in length probably indicates a correlation between the two processes. The presence of root primordia up to the apical meristem seems to indicate a direct formative effect and not a secondary result of the cessation of growth, since the root primordia are initiated in tissues at the apex, which are developmentally

immature.

### SUMMARY

 $\beta$ -naphthoxyacetic acid provokes a growth response in intact tomato plants in concentrations ranging from 1.0 to 0.01 per cent, while a 0.001 per cent solution in lanolin is without effect.

A 1.0 per cent paste causes a negative curvature below the point of application, be this on the stem or petiole, and a positive curvature in the treated region. A 0.1 per cent paste causes a negative curvature below the point of application and at first also where the paste contacts the tissues. The latter subsequently becomes positive. A 0.01 per cent paste is effective only in the treated area, causing a negative curvature.

The above reactions with different concentrations of  $\beta$ -naphthoxyacetic acid is explained on the assumption of dilution of the substance as it diffuses from the lanolin into the plant and from cell to cell,

The development of root primordia follows the application of 1.0 and 0.1 per cent pastes, both of which also inhibit the growth of treated tissues.

The rate of reaction is very rapid. The first noticeable effect occurs usually within one hour, and a very conspicuous reaction occurs after two hours.

### CYTOLOGY OF THE GENUS LESPEDEZA<sup>1</sup>

### W. P. Pierce

THE GENUS Lespedeza Michaux, according to Pieters (1934), includes about 124 species, of which 17 are indigenous to the United States. The majority are native to eastern Asia, particularly China, Japan, Siberia, and Manchuria. A few species have been reported from Australia, Java, and Mauritius. A member of the Leguminosae, the genus is placed by Taubert (1894) in the subfamily Papilionatae, tribe Hedysareae, subtribe Desmodiinae.

Cytological study of the subtribe Desmodiinae has been meager. Of 15 genera, only Lespedeza and Desmodium Desv. have been reported on to date, and the reports concern chiefly chromosome num-

1 Received for publication July 24, 1939.

The writer wishes to express his appreciation to Professor C. E. Allen, under whom this work was carried out, for his advice and many helpful suggestions during the study, and to Dr. D. C. Cooper for stimulating suggestions and for furnishing some of the material used in the investigation. Part of the work was done with the aid of an R. Melville Cramer Foundation Fellowship from Dartmouth College.

bers. In Desmodium the haploid number 11 has been found in four species: D. perpesium (Kawakami, 1930), D. grandiflorum (Cooper, 1936), D. canadense, and D. tortuosum (Senn, 1938).

In Lespedeza, Kawakami (1930) reported the haploid number as 9 in L. bicolor, L. cyrtobotrya, L. homoloba, L. Sieboldi, and L. Sieboldi var. albiflora. Cooper (1936) reported the diploid number as 18 in L. variegata and L. sericea, but 20 in L. tomentosa and L. stipulacea. In L. daurica he found the diploid number to be 36. For each of the species studied Cooper presents a short description of chromosome morphology and range of length. One pair of satellite chromosomes is present in L. variegata and L. tomentosa. Cooper suggests, in view of the numbers thus far determined in the genus, that nine is probably the basic number.

Senn (1938) attempts to relate chromosome number in the Leguminosae with taxonomic characters and with the herbaceous or woody habit; he dis-

cusses also the relation of polyploidy to geographic distribution. Although admitting the insufficiency of present information, he suggests that chromosome numbers in Lespedeza and Desmodium may aid in distinguishing these genera, the basic number for Lespedeza appearing to be 9 and that for Desmodium 11. He suggests that further investigation may show that in Amorpha and Lespedeza, the distribution of polyploids is conspicuously more northern than that of diploids. Yet he points out that such evidence is inconclusive, inasmuch as in ten genera, including Lespedeza, diploid species have a wider distribution than polyploids.

MATERIALS AND METHODS.—The plants used in the present study were grown from seeds obtained mostly from the U. S. Department of Agriculture, through the kindness of Dr. A. J. Pieters and Mr. Roland McKee of the Division of Forage Crops and Diseases. Some seeds were taken from specimens in the herbarium of the University of Wisconsin, and a few were collected from plants growing in the field.

To secure a reasonable percentage of germination, it was found necessary in almost all cases to scarify the seeds. Exposure to a temperature below freezing, as well as to intermittent sunlight, aided in the germination of the rather old seeds of a few species. Determinations of chromosome numbers were made in most cases from the primary roots of seedlings allowed to grow for a period of a week to ten days in sand, then fixed in Belling's, Karpechenko's, or Randolph's modification of Navashin's

Fig. 1-20.—All figures are of somatic equatorial-plate chromosomes from cells of root tips fixed in one of the Navashin fixatives, with the exception of fig. 10, which is of a dividing nucleus in a microspore, fixed in Carnoy's alcohol-acetic solution. All were drawn with the aid of a camera lucida. The magnification in all cases, ca.  $3000 \times -$  Fig. 1. L. bicolor. From a cell of the periblem (2n=22).—Fig. 2. L. bicolor. From a cell of the dermatogen.—Fig. 3. L. cyrtobotrya (2n=22).—Fig. 4. L. cyrtobotrya var. pedunculata (2n=22).—Fig. 5. L. violacea (2n=20).—

fluid, or in Flemming's medium solution. All gave fairly satisfactory results; perhaps the best were obtained with Randolph's formula.

Fixations of floral buds were made from plants growing in the field and in the greenhouse. Most species of Lespedeza produce both chasmogamous and cleistogamous flowers in the same inflorescence, usually the latter type only being fertile. The small size of the buds, and the presence of closely adherent hairy bracts, made fixation difficult. A variety of fixatives were tried, in some cases after pre-fixing in Carnoy's alcohol-acetic solution. To aid in penetration an aspirator also was used for short periods of time. It was finally apparent that satisfactory results could be secured only by partial dissection in a fixative under a binocular microscope.

Root tips were dehydrated with chloroform and imbedded in the usual manner. This method was found to harden buds to such an extent as to make sectioning very difficult. Dehydration with the aid of an anilin-cedarwood oil mixture proved more satisfactory since it avoids the use of the higher concentrations of alcohol. Sections were cut at a thickness of 8 to 10 microns. Smith's (1934) picric-acid modification of Newton's crystal violet-iodine was the stain most used for root-tip material. For floral buds the best results were obtained with Heidenhain's iron-alum haematoxylin.

The use of Belling's aceto-carmine method in the study of meiotic stages proved unsatisfactory, probably because of the extremely small size of the anthers

Observations.—Table 1 lists the species studied, seed collection number if the seed was acquired from the Department of Agriculture, chromosome number, and the author and date of each report of chromosome number. The species are arranged as far as possible to agree with Taubert's subdivision of the genus. Numbers listed under the present author's name are reported in this paper. Synonyms in parentheses are those retained in Index Kewensis.

Section Archilespedeza Taub., subsection Macrolespedeza Maxim.—L. bicolor Turcz. (fig. 1, 2).—The somatic (2n) chromosome number in this species, determined from division figures in the root tip, is 22. The chromosomes are well separated and easily counted. As appears from table 1, this number does not agree with that (n=9) reported for this species by Kawakami. For this reason the count here given was decided upon only after a considerable number of favorable equatorial plates were examined and drawn.

The chromosomes in this, as in most species of the genus, are small, varying in a typical complement from 1.5 to 3.0  $\mu$ . These measurements are presented with the realization that many factors, such

as the relative position of the cell in the root tip and the exact stage of contraction of the chromosome, may cause a considerable variation in chromosome length and width from cell to cell. For example, in figure 1, drawn from a cell of the periplem, the chromosomes appear somewhat longer and thicker than those in figure 2, from a cell of the dermatogen. Therefore the figures given denoting ranges of chromosome lengths may be considered useful in a relative sense only.

The chromosomes appear to fall into three general types (fig. 1a) according to the location of primary constrictions, the types not being sharply delimited. In some equatorial plates the constrictions are readily apparent; in others they are inconspicuous. Observations of the former type of figure would tend to indicate that in many cases primary constrictions are located at the region of a major bend in the chromosome. Secondary constrictions, although sometimes visible, were not recognizable in a sufficient proportion of cases to warrant discussion.

In the three main types of chromosomes referred to, the primary constrictions are, respectively, (A) median, (B) submedian, and (C) subterminal. In addition, chromosomes bearing satellites, designated as type (D), are often to be observed. Although lengths do not show very great differences, the chromosomes may further be distinguished as long, medium, and short.

In L. bicolor there appear to be at least three pairs of chromosomes of type A (median constriction), two long and one short. In this species most of the homologous pairs can be identified (fig. 1a). Type B (submedian constriction) is represented here by at least 3 pairs, all apparently of medium length. Two pairs of type C chromosomes (subterminal constriction) appear to be long, one pair very short, and one pair of medium length. A single short chromosome with an attached satellite was observed in several equatorial plates (fig. 2), but the homologous chromosome could not be identified. The approximate formula for a somatic complement (fig. 1a) may be represented: 2(3A + 3B + 4C + D).

L. cyrtobotrya Miq. 2n = 22 (fig. 3).—The chromosomes are similar in size and morphology to those of L. bicolor. The four types of chromosomes are again recognizable in the proportions: 2 (4A + 3B + 3C + D). Of type A two pairs are of medium length and two are short. All the type B chromosomes seem to be long or of medium length. It should be pointed out that it is difficult to distinguish with certainty, here as in other species, between chromosomes with median and those with submedian constrictions. The constrictions characteristic of type C are not very evident, but the bending of the chromosomes would indicate the presence of one long

pair, one of medium length, and one short. As in L. bicolor, one pair of type D chromosomes (d, d, fig. 3) is present. Here they appear distinctive because of the large size of the satellites, and of the fact that these D-type chromosomes are nearly as long as the longest in the complement. In this species also Kawakami has reported the haploid number 9. The somatic number here reported was based upon the examination of a considerable number of favorable figures.

L. cyrtobotrya var. pedunculata Nakai 2n=22 (fig. 4).—As would be expected, this variety corresponds fairly closely in chromosome size and form with the typical L. cyrtobotrya. The chromosome formula is 2(4A+3B+3C+D). The relative sizes of the chromosomes of type A and C are much the same as those in the typical form. The chromosomes of one pair of type B seem shorter in the variety. The greatest contrast was observed in chromosomes of type D, which are of only medium length and bear comparatively small satellites.

Subsection Eulespedeza Maxim.—L. violacea Pers. 2n = 20 (fig. 5).—Seeds were secured from a herbarium specimen collected in Grant County, Wisconsin, in 1934. The seeds germinated poorly, probably because of their age, and satisfactory division stages were few. The figure shows that the chromosome morphology of this species is not very distinctive. As nearly as can be determined, it has the 2 (3A + 4B + 3C). The chromosomes of type A consist of one long pair and two of medium length; those of type B of one short pair and three of medium length; those of type C of two long pairs and one pair of medium length. No constrictions were visible in a number of these chromosomes. In the equatorial plates examined, no satellite chromosomes were observed. Chromosome lengths range from 1.3 to 2.3 μ.

L. Stuvei Nutt. 2n=20 (fig. 6).—This species also is native to the United States. The count was made from six equatorial-plate stages, most of which showed unusually clear chromosome morphology. The chromosome formula is 2(4A+4B+2C+D). Of the chromosomes of type A, three pairs are long and one is short. Type B includes one long pair and two of intermediate length. Both pairs of type C appear to be fairly long. A single pair of short chromosomes bearing very small satellites was observed in three cases. Chromosome lengths range from 1.6 to  $2.5 \mu$ .

L. floribunda Bunge. 2n=22 (fig. 7).—In this Chinese species not only is the number the same in L. bicolor and L. cyrtobotrya, but there is apparent also a fairly close resemblance in the chromosome complements, as shown by the formula: 2(4A+3B+3C+D). Of type A there are one long pair, one of medium length, and two short. All three pairs of type B are of medium length. Those of type C are all long. The two type D chromosomes are of medium length, with no evident constrictions, and bear minute satellites. Chromosome lengths range from 1.5 to  $2.5 \mu$ .

L. virgata DC. 2n = 22 (fig. 8).—The somatic complement of this Asiatic species appears distinctive because more than half of the chromosomes are less than  $1.6 \mu$  in length. The range is from 1.1 to  $2.8 \mu$ , with a usual width of about  $0.5 \mu$ . The chromosome formula may be tentatively stated as 2 (5A + 3B + 3C). One pair of type A chromosomes are long, all the other pairs are short. Two pairs of type B are fairly long, the third pair is short. Of type C, one pair is fairly long, the other two pairs are short. No satellite chromosomes were observed.

L. repens Bart. 2n=20 (fig. 9).—The chromosomes of this native species appear somewhat thicker than in most other species, and constrictions are not evident in all cases. The following formula is therefore only tentative: 2(4A+3B+2C+D). Of type A there are two pairs of medium length, and two short. Two pairs of type B are of medium length, and one pair is long. Both pairs of type C are long. The single satellite chromosome shown in figure 8 is nearly as long as the longest and has a submedian constriction, the large satellite being attached to the longer arm. Both satellites were observed in another case. Chromosome lengths vary from 1.5 to 3.0  $\mu$ .

L. sericea Benth. n=9 (fig. 10).—This count was taken from division figures of the microspore nuclei, confirming the diploid count of 18 by Cooper. As figure 10 suggests, not much can be said about the morphology of the chromosomes since they are unusually contracted, probably in consequence of fixation in Carnoy's alcohol-acetic solution. It is possible, however, to recognize two or three chromosomes of type A, several of type C, and at least one of type B. None of type D were observed. A few first and second division figures were seen but were too crowded for an accurate count.

L. capitata Michx. 2n = 20 (fig. 11).—Seeds of this native species were obtained from plants collected at several stations in Dane County. Since as many as eight varieties have been described, it was thought that a study of the chromosome complements of two of the most divergent types might aid in evaluating such varietal differences. One type had ovate, very pubescent leaves, the other lanceolate glabrous leaves. Although seeds from cleistogamous fruits only were sown, the plants obtained from them showed considerable variation from the parental types, indicating a probable high degree of heterozygosis. The somatic chromosome number was found to be the same in both forms. The chromosome morphology also is practically identical in the two. Again at least four pairs of type A chromosomes are distinguishable; here they are of varying lengths. Of type B only one pair could be identified with certainty; two or more pairs of type C, one pair long and one of intermediate length. A single long chromosome of type D, with a small satellite, was recognized (fig. 11). The chromosome lengths varied from 1.8 to 2.8  $\mu$ .

L. variegata Cambess. (L. juncea Pers.). 2n = 20 (fig. 12).—This number is presented tentatively,

four clear equatorial plate figures having been drawn and studied. Since it does not agree with the number previously reported by Cooper, additional plants might well be studied to confirm one or the other count. It may be obvious to point out that the number of chromosomes in a given figure may be variously interpreted by different workers. For example, an apparent end-to-end association of two chromosomes may in reality be a single chromosome with a deep constriction. This difficulty of interpretation often appears in species of Lespedeza even in otherwise favorable preparations. The specific appellation itself suggests the possibility of the existence of races with different chromosome numbers. A study of the chromosome morphology seems to show the following formula: 2 (3 or 4A + 2 or 3B+3C+D). The chromosomes of type A seem mostly short, although one pair is of medium length. Those of type B are of medium length. Of type C two pairs are long and one pair is of medium length. The chromosomes of the single pair of type D appear short in figure 12, but in another plate seen they were clearly of medium length. Choromosome lengths vary from 1.2 to 3.0  $\mu$ .

 $\bar{L}$ . hirta (L.) Hornem. (= L. villosa Pers.). 2n=20 (fig. 13).—The chromosomes are as large as those of any species studied, with lengths ranging from 1.6 to 3.3  $\mu$ , and with an average width of 0.7  $\mu$ . The chromosome formula may be expressed: 2 (4A + 3B + 2C + D). Type A consists of two long pairs and two of medium length; type B, of two long pairs and a pair of medium length; of type C, a short pair and a long pair can be identified; a single short pair of type D is present, with no evident constriction.

tions and bearing minute satellites.

L. pilosa Sieb. et Zucc. 2n=20 (fig. 14).—In contrast to the last named species, the somatic chromosomes of this one are small, ranging from 1.5 to 2.6  $\mu$  in length, and widths of only about 0.3  $\mu$ . The chromosome formula is 2 (4A + 2B + 3C + D). Type A includes a long pair, two pairs of medium length, and one short pair; type B, one long pair and one of medium length; type C, one long pair, one of medium length, and a single short pair. The chromosomes of the single pair of type D are as short as any in the complement, if they are not the shortest; their satellites are of medium size.

Section Campylotropsis Bge.—L. macrocarpa Bunge. 2n=22 (fig. 15).—The chromosome complement of this species appears distinctive in that nearly half of the chromosomes are less than  $2 \mu$  long. However the range of lengths is about the average for the genus, varying from 1.5 to 3.0  $\mu$ . Widths are relatively high, averaging  $0.6 \mu$ . Chromosome morphology therefore is not very distinctive, but at least a few of each type may be distinguished. There seem to be four pairs of type A chromosomes, one long pair and three short. Three chromosomes resemble type B, indicating that at least two pairs of medium length are present. Type C is represented by at least two pairs, both long. The single chromosome of type D seen seems to have

a median constriction and bears a rather small satellite.

Section Microlespedeza Maxim.—L. striata var. Kobe 2n=22 (fig. 16).—This variety was introduced from Japan by J. B. Norton in 1919. Chromosome size appears to be rather small, with lengths varying from 1.3 to 2.3  $\mu$ . The morphology appears distinctive enough to present a formula: 2 (4A +4B+3C). All four pairs of type A chromosomes are short (1.5  $\mu$  or less). Three pairs of type B are short, and one pair is long. Two pairs of type C are long, the other pair being of medium length. No satellite chromosomes were observed.

L. stipulacea Maxim., although listed as synonymous with L. striata Hook. et Arn. by the Index Kewensis, would appear to be a valid species on the basis of the chromosome number (2n = 20) as given

by Cooper.

Section Uncertain.—The following species have not been assigned to any section of the genus, and lack of flowering material has as yet prevented any attempts to place them. In a few cases a morphological similarity to species mentioned above has been noted.

L. procumbens Michx. 2n = 20 (fig. 17).—This native species, because of its similarity to L. repens, should probably be included in the subsection Eulespedeza. Chromosome size in general seems to be intermediate, with a range of length from 1.6 to  $2.9 \,\mu$ . The chromosome formula may be expressed: 2 (4A + 3B + 2C + D). Three pairs of type A chromosomes are of intermediate length or slightly longer, and one pair is short. Two pairs of type B are long, and one pair is of medium length. The single type D chromosome shown in figure 17 is short; its satellite is of medium size.

L. frutescens (L.) Britton. 2n = 20 (fig. 18).— This species also is native to the United States and resembles L. procumbens in both size and form of chromosomes. Here, however, although the chromosome formula is the same, two pairs of chromosomes of type A are long, and two pairs are somewhat shorter. Of type B there are one long pair, one short, and one of intermediate length. One pair of type C is long, one pair short. The two chromosomes of type D are long, with approximately submedian constrictions and satellites of medium size.

L. latissima Nakai. 2n = 20 (fig. 19).—Very little appears to be distinctive about the somatic chromosomes of this Asiatic species. Chromosome lengths range from 1.6 to  $3.5 \mu$ . Positions of constrictions indicate that the formula is: 2 (3A + 3B + 3C + D). The three pairs of type A chromosomes are, respectively, long, medium, and short. Those of type B and C show a similar range of lengths. The single pair of type D is short, with probably median constrictions and large satellites.

L. inschanica (Maxim.) Schind. 2n = 20 (fig. 20).—The chromosomes of this species resemble closely those of L. latissima. Lengths show a slightly different range, from 1.3 to 3.0  $\mu$ . The approximate formula is 2 (3 or 4A + 2 or 3B + 3C + D). The

chromosomes of type A are all long, those of type B all of intermediate lengths; of type C, two pairs are short and one pair is of medium length. The two type D chromosomes are of medium length with fairly small satellites.

L. Maximowiczii Gandog. (= L. bicolor Turcz.). 2n=22 (fig. 21).—Chromosome lengths vary from 1.5 to 2.6  $\mu$ . There appear to be more chromosomes of type C than usual, as shown by the formula: 2(3A+3B+4C+D). Range of lengths: Type A, two long pairs and one of medium length; type B, three pairs of medium length; type C, three short pairs and one of medium length; type D, one fairly long chromosome seen, with a submedian constriction and a small satellite.

L. Thunbergii Nakai. 2n=22 (fig. 22).—The chromosome formula for this species is 2 (4A+3B+3C+D). There appear to be one long pair of type A, one of medium length, and two short pairs. Of type B two pairs are long and one pair is intermediate in length. Those of type C show a similar range of lengths. Only one chromosome of type D is identifiable in figure 22. It is of medium length, with a median constriction, and bears a fairly large satellite. Chromosomes vary in length from 1.1 to  $2.6 \mu$ .

L. virginica (L.) Britton. 2n = 22 (fig. 23).— This is the only American species studied whose somatic chromosome number is other than 20. Its chromosome formula is 2 (4 or 5A + 3 or 4B + 3C). There are two or three long pairs of type A chromosomes, and two short pairs. Of type B there are two or three long pairs and one pair of medium length. The three pairs of type C are, respectively, long, medium, and short. No satellite chromosomes were observed. Lengths of chromosomes vary from 1.2 to  $3.0 \mu$ .

L. japonica var. intermedia (Nakai) Nakai. 2n = 22 (fig. 24).—The chromosome formula is 2 (4A + 3B + 4C). Of the type A chromosomes, one pair is long, two are short, and one is of intermediate length. The three pairs of type B are of medium length. Three pairs of type C also are of medium length and one pair is long. No satellite chromosomes were observed. Range of lengths, 1.3 to 3.1  $\mu$ .

L. robusta Nakai 2n = 22 (fig. 25).—Although observations of this species to date have been limited to fairly young plants, the size and shape of the leaves, as well as the habit of growth, would suggest that it is a member of the subsection Macrolespedeza. The chromosome morphology is similar to that of several other 22-chromosome species, the formula being the same as in L. cyrtobotrya and L. Thunbergii: 2 (4A + 3B + 3C + D). Here the type A chromosomes are represented by two long pairs, one of medium length, and one short. Of type B, two pairs of medium length, and one pair is long. Of type C, also, there are two pairs of medium length and one long pair. The two of type D are of medium length with no evident constrictions, and bear medium-sized satellites. Chromosome lengths vary from 1.3 to 2.7  $\mu$ .

L. daurica Schind. 2n = ca. 44 (fig. 26).—This Asiatic species is of interest in that it is the only one of the genus which has been shown to be tetraploid. It is to be noted that there is a considerable discrepancy between the count here given and that reported for this species by Cooper. For this reason counts were made from root tips taken from 8 or 10 individual plants. It appeared from a study of a considerable number of figures that the chromosome number in these plants must be either 42 or 44. The higher number is probably the correct one. In view of the wide discrepancy in counts it is possible that races occur with different chromosome numbers.

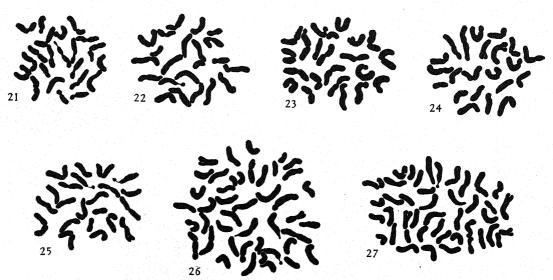

Fig. 21-27.—Fig. 21. L. Maximowiczii (2n = 22).—Fig. 22. L. Thunbergii (2n = 22).—Fig. 23. L. virginica (2n = 22).—Fig. 24. L. japonica var. intermedia (2n = 22).—Fig. 25. L. robusta (2n = 22).—Fig. 26. L. daurica (2n = 21).—Fig. 27. L. daurica var. shimadai (2n = 21).

There is no correlation between chromosome numher and plant or organ size, since several members of the section Microlespedeza are considerably larger in both plant and organ size than is L. daurica. Nuclear and cell size do appear to be somewhat larger than in the other species, as might be expected. The chromosomes are similar in general size and morphology to those of the diploid species. Lengths vary from 1.0 to 3.0 \(\mu\). Since constrictions were not evident in many of the chromosomes, no attempt is made to present a formula. However, all the various types of chromosomes may be identified. There appear to be about 8 pairs of chromosomes of type A. In no figures examined was more than a single pair of type D chromosomes found. They appear to be of medium length, with satellites of medium size. In one case a division figure with about twice the usual number of chromosomes was observed in the dermatogen of the root.

L. daurica var. shimadai (Masamune) Masam. and Hosokawa. 2n = ca. 44 (fig. 27).—This variety differs only slightly in leaf shape from the typical form of the species. An examination of figure 27 will show that in the chromosome size and morphology also, the type and variety are practically identical.

Discussion.—The chromosome numbers of approximately one-fourth of the known species of Lespedeza have been determined. The number of species studied is therefore sufficient to warrant suggestions as to the basic numbers for the genus or its respective sections. Table 2 summarizes the reports to date on the chromosome numbers in the genus. In three cases, conflicting numbers were previously reported, but they are omitted from the table.

TABLE 2.

Haploid number	Number of speci and varieties	es Percentage of total
9	5	16.1
10	13	41.9
11	11	35.4
22	2	6.4
	<del></del>	
	31	99.8

Nine of the seventeen species listed by Pieters as native to the United States have a haploid count of 10, one species only (L. virginica) having the count n=11. Of the remaining species, most of which are Asiatic, only about 12 per cent (24) have been studied. Of these species 13 have the haploid number 11, 3 have 10, and 5 have 9. (L. bicolor and L. cyrtobotrya, previously reported by Kawakami as n=9, were found to be 2n=22 by the present author. Similarly, L. variegata, reported by Cooper as having 2n=18, appears to have 2n=20.)

It seems likely, therefore, that the basic number for the American species of Lespedeza is 10. For the rest of the genus it may well be that the basic number is 11, although such a conclusion would necessarily be based on rather limited data.

For the genus as a whole it would appear that an increase or diminution in chromosome number of the haploid set by one or two (perhaps in consequence of fragmentation or translocation) might account for the occurrence of such closely similar numbers. The low frequency of the number 9 may indicate a derivation from one of the other numbers.

It appears doubtful whether, as suggested by Senn, chromosome numbers alone can aid greatly in distinguishing species of Lespedeza from those of Desmodium. The somatic numbers of only three species of Desmodium (in each case 22) have been determined to date. Yet, if subsequent work shows that the number 22 is of constant occurrence in that genus, it may be significant that of the American species of Lespedeza examined cytologically, all but L. virginica have the diploid number 20.

The chromosomes vary but little as to number. size, and form among species or even among sections of the genus. The single species of the section Campylotropsis studied, L. macrocarpa, has the diploid number 22. The single species (L. striata var. Kobe) of the section Microlespedeza has the diploid number 20. The few species studied in the subsection Macrolespedeza appear to be constant as to number (2n = 22), and in general as to chromosome size. Within the other sections or subsections of the genus. however, variations in number occur. Satellite chromosomes sometimes show what may be specific differences in length, in location of constriction, and in size of satellites. Coonen (1938) has noted similar variations in satellite size and in length of setae in species of Ranunculus.

The apparent presence of a single pair of satellite chromosomes in *L. daurica* may indicate that this is an allotetraploid species derived originally from a cross between a 22-chromosome species with a pair of satellites and one without such a pair or with a pair which has lost its satellites.

### SUMMARY

The chromosome number has been determined for 22 species and three varieties of the genus Lespedeza. In four out of five species whose numbers have previously been reported, the counts disagree with those here given.

In the section Archilespedeza, subsection Macrolespedeza, L. bicolor, L. cyrtobotrya, and L. cyrtobotrya var. pedunculata have the somatic chromosome number 22. In the subsection Eulespedeza the following chromosome number determinations were made: L. sericea, n=9; L. violacea, L. Stuvei, L. repens, L. capitata, L. variegata, L. hirta, and L. pilosa, 2n=20; L. floribunda and L. virgata, 2n=22.

L. macrocarpa, in the section Campylotropsis, has the number 2n = 22. In the section Microlespedeza, L. striata var. Kobe has the number 2n = 20.

The remaining species and varieties investigated have not, up to the present time, been assigned to

any section of the genus. The chromosome numbers are as follows: L. procumbens, L. frutescens, L. latissima, and L. inschanica, 2n = 20; L. Maximowiczii, L. Thunbergii, L. virginica L. japonica var. intermedia, and L. robusta, 2n = 22; L. daurica and L. daurica var. Shimadai, 2n = ca.44.

It is suggested that the basic chromosome number for the American species of the genus is 10. For the rest of the genus, on the basis of work to date, it appears likely that the basic number is 11, although n=9 has been reported for certain Japanese species.

The somatic chromosomes are small and fairly similar in size and form as among species and even sections of the genus. The chromosomes display constrictions in median, submedian, and subterminal positions. Chromosomes of these types appear in varying proportions in all species studied. Satellite chromosomes sometimes appear to show specific differences in length, position of constriction, and in size of satellites.

## THE SIGNIFICANCE OF CERTAIN ABNORMALITIES IN EQUISETUM 1

### Robert H. Tschudy

Abnormality and irregularity in this genus are by no means uncommon. Many workers, including Schaffner (1927, 1928, 1929, 1933), Kashyap (1930), and Allen (1928), have described and listed some of these. I have found two additional types of abnormality which I hope will help to clear up some of the differences in opinion relative to an interpretation of the cone and sporangiophore structure insofar as they relate to problems of structure or phylogeny.

IDEAS CONCERNING THE CONE AND SPORANGIO-PHORE STRUCTURE OF EQUISETUM.—There are two schools of thought concerning the structure of the cone of Equisetum. One, championed by Browne (1912, 1915, 1920, 1921, 1923, 1927, 1933) and others, contends that the cone is made up of a shortened axis consisting of nodes and internodes and that the position of the sporangiophore designates the node. This is the more widely accepted view. Opposed to this is Barratt (1920) who contends that the arrangement of the xylem strands and the mode of origin of the sporangiophore traces fail to support the view that the fertile axis is made up of alternating nodes and internodes.

The theses concerning the nature of the sporangium-bearing organ are more numerous and varied. Eames (1936) indicates that the structure has been called a lateral branch bearing a whorl of sporangia; the fertile lobe of a dorsiventrally divided sporophyll, the ventral lobe of which is either lost or is also fertile; the stalk of a raised and divided sporangium; a sporophyll; an organ sui generis.

<sup>1</sup> Received for publication June 21, 1939.

To obtain an idea of the ratiocination behind the possibilities, we must consider the situation among the fossil progenitors of the group. Present-day Equisetae were most certainly derived from the almost identical Equisetites of the Mesozoic. These in turn probably were derived from the Calamites or their forerunners. One of the difficulties of interpretation of the sporangiophore and cone structure of present-day Equisetae lies in the presence of bracts in the Calamitaceae of the Coal Measures and the absence of bracts in Equisetum. What became of the bracts in the Calamarian cone?

When we consider the fossil representatives in the order of their antiquity, we find the oldest known ancestor of the group, Archaeocalamites, in the upper Devonian strata. This genus bore cones and whorls of peltate sporangiophores very similar to those found in present-day Equisetae. Bracteate cones with one or two exceptions do not occur below the Coal Measures and the Permian strata. Here are found two examples of Calamitaceae which should be mentioned. One is Calamostachys which bore fertile shoots consisting of whorls of peltate sporangiophores alternating with intermediate and equidistant verticils of sterile bracts. The second is Palaeostachya which bore sporangiophores not inserted midway between sterile bracts, but in the axil of each verticil of bracts. However, the xylem trace of the sporangiophore in this genus traversed the internode for some distance and then was reflexed downward almost to its point of origin before entering the sporangiophore.

Smith (1938) is of the opinion that in presentday Equisetae the annulus is all that remains of the Calamostachys type of bract-in other words, that the bracts have become lost. He is very definite concerning the non-foliar nature of the sporangiophore. Browne (1927) postulates that the Calamarian cone is a modification of the Archaeocalamitean bractless cone and that the type of greatest antiquity persists to the present-day in Equisetum. Thus the Equisetaceae are not to be considered direct line descendants from the Calamites, but a very early offshoot. The possibility that the Equisetaceae were derived from a Sphenophyllaceous ancestry lies in the assumption that the sporangiophore is part of a dorsiventrally bilobed sporophyll. The more recent Sphenophylls had highly complex cones bearing peltate sporangiophores on one or both lobes of a dorsiventrally bilobed leaf. There is little evidence from a study of the anatomy of the cone (Browne, 1927) or of the sporangiophore to indicate that the sporangiophore of Equisetum has arisen, during phylogeny, from the union of the dorsal and ventral lobes of a sporophyll. Browne (1920) has shown that the anatomy of the sporangiophore indicates that it is a whole organ. She has also shown that two successive whorls cannot be considered as two lobes of a bilobed leaf.

The above considerations give us little insight into the actual nature of the fertile organ. In my opinion, the view held by Barratt (1920) that the present-day sporangiophore is an organ sui generis has little to support it. The evidence I propose to submit indicates that the sporangium-bearing organ is a modified leaf.

Abnormalities found in Equisetum telmateia ehrh.—These abnormalities are of two different types. The first, found only once, is an apparent phyllody of several whorls of sporangiophores occurring midway on an otherwise normal cone. The second type consists of intercalary cones or cones having the vegetative axis resume growth and develop to a greater or less extent above the cone. This type is so common that twenty specimens have been collected on an afternoon's walk on the campus of the University of Washington.

Phyllody of sporangiophores in Equisetum, to my knowledge, has never been reported. In the single cone in which it occurred (fig. 1, 3) there was no evidence of mechanical, insect, or fungal injury. The first five "nodes" above the annulus bore normal sporangiophores with normal sporangia. A region made up of from four to five "nodes" was abnormal, bearing no sporangia on the more or less filiform appendages. Some of these appendages were short and stubby, appearing much like the stalk of a sporangiophore without the enlarged cap-like sporangium bearing tip. Others were somewhat swollen at the tip, but completely sterile. Still others were long and tapered growing for a distance at right angles to the cone, then bending upward. Some of these latter were united at the base, giving somewhat the appearance of a segment of a leaf sheath. Above this region the cone bore normal sporangiophores and normal sporangia.

Intercalary cones have been reported only once by Kashyap (1930). He found one specimen of E. debile bearing such a cone. Intercalary cones, usually found in the upper one-third of a vegetative branch, consist of from two to a dozen or so more or less well-defined whorls of sporangiophores. Of the forty or fifty intercalary cones that I have collected, those that are made up of but two to four nodes are the most interesting. They are without exception abnormal to some degree and tend, more than the larger cones, to elucidate the nature of the sporangiophore (fig. 8, 18).

Figure 8 shows a cone which appears to lack an annulus. The lowest node shown consisted of a large leaf sheath which completely obscured the three nodes immediately above it. This has been cut away to show the structures. Possibly there is only a partial annulus as evidenced by the apparent free lobes intermediate between the full leaf sheath and the first complete whorl. The two lobes or expanded structures to the left are sterile, while the two to the extreme right are cylindrical appendages bearing on or near their apices a thickened expansion to which sporangia are affixed. The lowest complete fertile whorl is made up of sporophylls strikingly similar to those seen in figure 18. Though somewhat aberrant, they are more nearly peltate than those of the node next above. There are comparatively few sporangia present on this node (the second from the top) and as a whole it takes on somewhat the appearance of a distorted, split-up leaf sheath. The uppermost node figured is almost normal. Branches penetrate through its base in a normal fashion, although a complete whorl of branches is absent. The sheath itself is split down one side to a point slightly below its point of attachment to the node.

Nodal nature of cones.—The arrangement of the sporangiophore whorls in relation to vegetative nodes is indicated in figure 2. The sporangiophores are crowded into about eight rows on a little more than two-thirds of the perimeter of the stem and absent on the remainder. In their stead leaves, some fully an inch long, arise from a continuation of the sporangiophore whorl.

The nodal nature of an intercalary cone is also shown by the arrangement of tissues in a longitudinal section (fig. 7). This is a median section through a cone similar to that drawn in figure 18. The vascular supply, as well as the nodal septae and even the lignified so-called nodal rings which are present in normal nodes, are shown. The lack of nodal septae and the irregularity of departure of traces in the normal cone led Barratt (1920) to conclude that the cone axis is not made up of nodes and internodes. I am aware that the structure and arrangement of elements in an intercalary cone of only three nodes cannot prove the nodal condition of terminal cone axes. However, the gradation from intercalary cones consisting of one or two nodes to almost normal appearing intercalary cones made up of many nodes.

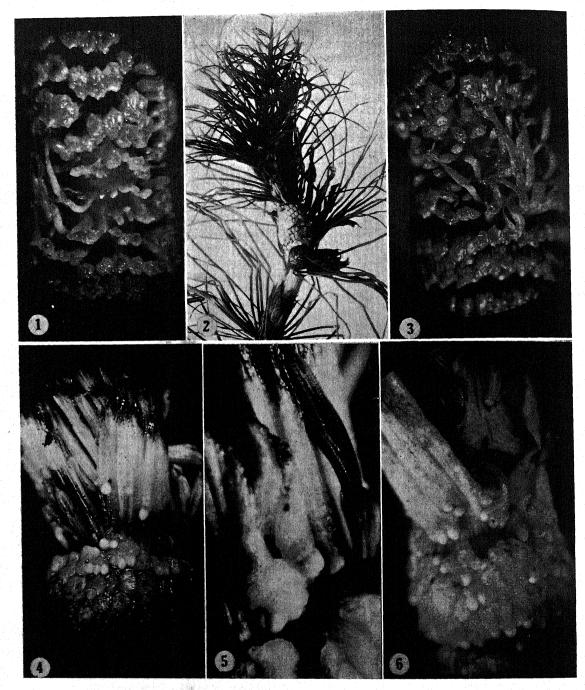

Fig. 1-6.—Fig. 1. An enlarged photograph showing the phyllody or sterility of a segment of an otherwise normal cone.—Fig. 2. An intercalary cone which bears normal leaves as continuations of the fertile nodes. The cone is completely sterile on the side which bears the leaves.—Fig. 3. Another view of the same cone as seen in fig. 1.—Fig. 4. An intercalary cone showing sporangia on the back of the first sheath of leaves above the cone.—Fig. 5. An enlargement of several sporophylls bearing ligulate appendages.—Fig. 6. Another intercalary cone bearing sporangia at the base of the first leaf sheath above the cone. Note that in many cases the sporangia in the cone proper are not covered by the growth of the sporophylls.

coupled with the occasional phyllody of part of a fertile node, are strongly presumptive evidences that the sporangiophores are borne at nodes. The sporangiophores.—Figures 9 to 16 have been arranged to show a complete series of sporangiophores ranging from an almost normal quasi-peltate

sporangia on the outer surface. The drawings were made with the aid of a camera lucida and in most cases show both the inner and outer surfaces of the

sporangiophores.

Figure 9 is the most nearly normal. It is peltate, but the stalk is somewhat more robust than normal and the top surface is irregular and furrowed and not raised, swollen, and angular as are entirely normal sporangiophores. Figure 10 shows the lateral union of at least two sporangiophores bearing many sporangia. A short leaf-like protuberance is present as an extension of the top of the sporangiophore, indicating that practically the whole leaf or segment of a whorl of leaves has been reduced to sporangiophore. Broad sporangiophores of this type often possess two or more vascular strands. Figure 11 is an example of a further extension of the leaf or less reduction of leaf to sporophyll. Here the sporangia appear to be borne on the inner or adaxial surface of the leaf. A photograph of this type of sporangio-

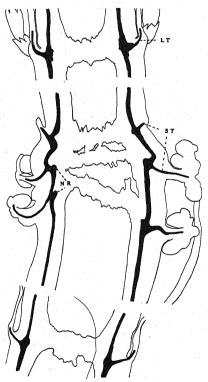

Fig. 7. Longitudinal section through an intercalary cone and adjoining stem. Vascular tissue in black. The long internodes have been omitted and are indicated by the breaks. nr, nodal rings; lt, leaf trace; st, sporangiophore trace.

phore is shown in figure 5. Figure 12 is practically a counterpart of figure 11, except for the fact that the ligulate extension of the leaf is more pronounced and the number of sporangia in relation to the size of the sporangiophore is much reduced. Figure 13 is an almost sterile segment of a supra-annular whorl of sporangiophores. This segment is, in appearance,

very like a segment from an abnormal annulus. In figure 14 the single sporangium is borne on the outer or abaxial surface of the leaf-like appendage. It is well known that the normal sporangia initials arise at the top of the young peltate appendage and, by

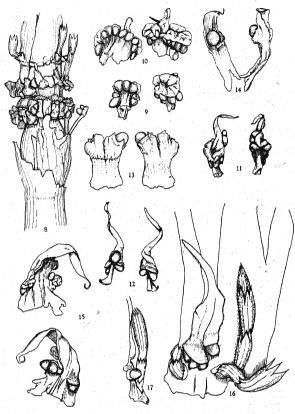

Fig. 8-17.—Fig. 8. An intercalary cone of two nodes and an abortive annulus.—Fig. 9-13. Inner and outer views of sporophylls and their gradation into leaf segments as the number of sporangia decreases.—Fig. 14. Sporangium borne on outer surface of leaf, and three sporangia.—Fig. 16-17. Sporangiferous leaf segments through whose bases lateral branches have penetrated.

the subsequent growth of tissue between them, are eventually pushed around underneath the sporangiophores' protecting edges, with the final appearance of being borne on the adaxial surface.

That the origin of sporangia on normal and abnormal or leaf-like sporangiophores is identical may be inferred from the above. A lateral view is given of this sporangiophore, showing how prominent the adaxial sporangia appear when they arise near the center of a sporangiophore rather than near its edge. The same phenomenon is observed in figure 15, a much larger, more leaf-like example. Here the sporangia are borne near the edges of the leaf but definitely on the outer surface. An extreme example of phyllody of sporangiophores is shown in figure 16. Here the sporangia are borne on the back of the leaf. At the point of insertion of the sporangium there is a swelling, while above the sporangium the leaf seg-

ments are somewhat reduced in size. The presence of sporangia on almost normal or normal leaf segments is often encountered on the first whorl of leaves above an intercalary cone (fig. 4, 6). In some cases lateral branches may be seen penetrating the base of the sheath, while in others the branches may be absent or, due to the looseness of the sheath, may grow up inside the sheath. Figures 16 and 17, and less clearly figure 4, show the penetration of branches through the fertile leaf segments. On one sheath (fig. 16) four sporangia are seen subtending an apparently stunted portion of the leaf. It will be noted that the sporangia are inserted above the level

Fig. 18. An intercalary cone bearing two nodes of abnormal sporangiophores and normal sporangia. The annulus is partly sporangiferous.

at which the branches penetrate the leaf sheath. In no case, even when sporangia and branch were in proximity, was there the slightest evidence that sporangia are ever borne on lateral axes.

The non-commital term "sporangiophore" has been given to the fertile organ in Equisetum because morphologists have been unable to agree on the nature or origin of this structure. In view of the evidence cited above, I propose that the more descriptive and accurate term "sporophyll" be used.

The annulus.—Some workers are willing to concede that the annulus is a reduced whorl of leaves, yet would not be willing to ascribe to the supraannular whorls the same derivation. I can find no reason for concluding that the supra-annular whorls are any different from the annulus, particularly in the abnormal intercalary cones that I have examined.

Several examples have been seen of a sporangiferous annulus bearing many vascular strands which are continuous with the vascular system of the stem and which end at the base of the sporangia. Barratt

(1920) states that the lack of vascular supply to the annulus, or even to abnormal fertile annuli, is an argument against the foliar nature of the annulus. This argument has been discounted by Browne (1920) and by the present observations.

Figure 18 shows an intercalary cone made up of two nodes and a so-called annulus. The annulus is partially but not completely sporangiferous. When the cone is reduced to the extent seen in this figure and figure 8, the normal appearing peltate sporophyll is universally absent. Some of the appendages are sterile; some bear sporangia on their abaxial face. Sporangia are not at all hidden but appear as excrescences in almost any position.

When an annulus is partly sporangiferous, the leaf sheath at the next node below is often modified. The portion of the leaf sheath below the sterile part of the annulus is normal, while the portion directly below the fertile part of the annulus is often reduced, sometimes to the extent of appearing no different from an annulus itself.

THEORETICAL CONSIDERATIONS.—An examination of the abnormalities figured shows that as the number of sporangia per sporophyll decreases, the more leaf-like the sporophyll tends to become. Is this lack of growth of the expanded leaf due to a lack of food? Do the sporangia have some mechanism for commanding the food supply to their exclusive use, or does the sporangium or its contents produce some substance which on diffusing from the sporangium produces a thickening of the sporophyll—a proliferation of tissue? It is a fact that an increase in the number of sporangia in general produces an increase in thickening and a more flattened peltate structure, tending to push the sporangia laterally and inward, resulting in a certain amount of protection to the sporangia as well as producing a decrease in the foliar appearance of the sporophyll. Support for the implication that either the food supply is commandeered or that a substance diffuses from the sporangia is found when an examination of the intercalary cones is made, for when the sporangia are borne on the leaves of one whorl, the sporophylls below are more nearly normal than they are on the first whorl (fig. 6). Does the cone or fertile segment produce some substance which diffuses downward to form the annulus or, more precisely, to inhibit the growth of leaves and branches from this node and the node below? A consideration of the situation present in Equisetum sylvaticum makes the query sound less fantastic, for here the fertile stem develops branches only after the cone has shed its spores and dried up. A careful examination of Equisetum telmateia in the field shows that here also a great many fertile branches become vegetative after the cone has shed its spores.

### SUMMARY

A discussion of the theories concerning the origin of the cone and sporangiophore of Equisetum is given.

Two types of abnormal cones found in Equisetum telmateia Ehrh. are discussed—i.e., the phyllody of a segment of an otherwise normal cone and the occurrence of intercalary cones midway on an otherwise vegetative stem.

The nodal nature of the intercalary cones was demonstrated by a section through one of them showing nodal septae and by one which developed sporophylls on one side of the stem and sheath leaves at each node on the other side.

A complete series of sporophylls ranging from normally peltate ones to very much expanded normal sheath leaves bearing but one or two sporangia is figured. This series demonstrates that the sporangia arise on the outer surface of the sporophyll and are pushed around to the inner by the growth or hyperplasia of the cells immediately surrounding them. As more sporangia are produced, the hyperplasia increases, at the same time decreasing the amount of leaf-like appendage until in the ultimate condition the ligulate appendage is lost and the sporophyll takes on the peltate appearance.

It is suggested in referring to the sporangium bearing structure in *Equisetum* that hereafter the term "sporophyll" be used in place of the non-committal, less exact term "sporangiophore."

# EARLY ROOT AND SHOOT GROWTH IN TWO VARIETIES OF AVENA SATIVA IN RELATION TO GROWTH SUBSTANCES $^{\rm 1}$

## Samuel Kaiser and Harry G. Albaum

GROWTH DIFFERENCES between varieties and species which have or are presumed to have a simple genetic basis constitute an excellent field for the study of the manner in which certain genetic factors operate in producing their effects. Such differences have been investigated by van Overbeek (1935), Lehmann (1936), Hinderer (1936), Graze and Schlenker (1936), and others; the importance of studying them has been repeatedly emphasized by Sinnott (1939). The present contribution attempts to add to our knowledge on this subject by presenting pertinent data concerning the growth of roots and shoots in two varieties of oats and the effects of a synthetic growth substance (3-indole acetic acid) on their growth.

MATERIALS AND METHODS.—The two varieties of Avena sativa used in these experiments, Black Norway and Fulghum, were obtained through the cour-

<sup>1</sup> Received for publication June 5, 1939.

tesy of Dr. G. M. Reed of the Brooklyn Botanic Garden. The oats were dehusked, soaked for two hours in tap water at room temperature, and illuminated for several hours. They were then germinated for twenty-four hours in an incubator maintained at a temperature of 25°C. At the end of this time, the young seedlings were transferred to the test solutions in 400 cc. beakers. The beakers were first lined with filter paper and received 50 cc. of the test solutions (tap water in the control beakers) which the filter paper absorbed. Twelve to fifteen young seedlings were carefully inserted between the filter paper and the glass of each beaker (fig. 1), the beakers were covered with Petri dish covers and transferred to the incubator or left uncovered and placed in a light-proof humid glass chamber. Under these conditions, the seedlings continued their growth, the primary and secondary roots growing straight in most cases so that repeated measure-

ments could be made through the glass without difficulty and without disturbing the plants. The length of the longest root was used as a criterion of total root growth (Lane, 1936). Shoot measurements were taken from the point of emergence from the grain to the coleoptile tip and thus included the length of the mesocotyl as well as the coleoptile. (All figures are averages of at least ten plants.) Final measurements on the length of shoots and number of

roots were made at the close of each experiment by removing the plants from the beakers.

The stock auxin solution was prepared by dissolving 3-indole acetic acid (Eastman Kodak Co.) in distilled water with slight heating. The concentrations employed in these experiments, made by diluting the stock solution, ranged between 0.002 mg./l. and 50.0 mg./l.

RESULTS.—Root growth.—Normal growth for the roots of the two varieties under the conditions of these experiments is represented by the figures in table 1 (control column). It will be noted that Black Norway grows more rapidly than Fulghum. The average rate of growth (final length of the longest root divided by the growth period) is 1.09 mm./hr. for Black Norway and 0.84 mm./hr. for Fulghum. In another experiment the figures were 1.05 for Black Norway and 0.85 for Fulghum.

Shoot growth.—The normal growth measurements on the length of the young shoot (mesocotyl

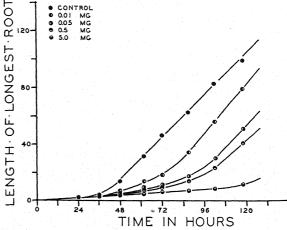

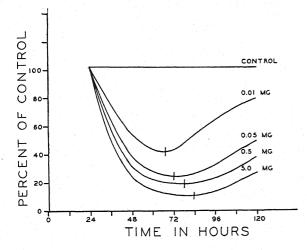

Fig. 2A (above). Effect of different concentrations of 3-indole acetic acid on the length of the longest root in Black Norway.

Fig. 2B (below). Effect of different concentrations of 3-indole acetic acid on the length of the longest root in Fulghum.

plus coleoptile) in the two varieties are shown in table 4 (control column). Shoot growth is seen to be slower in Black Norway than in Fulghum (0.24 mm./hr. as compared to 0.36 mm./hr.). A negative correlation thus exists between the rate of root growth and the rate of shoot growth in these two varieties.

Effects of auxin treatment; 1. Root length.—The results in a typical case of the treatment with 3-indole acetic acid on root growth using concentrations from 0.01 mg./l. to 5.0 mg./l. are given in full in table 1 and are shown graphically in figures 2A and 2B. It will be noted that in both varieties all concentrations of the growth substance bring about inhibition for a time, after which the roots begin to grow rapidly again, in all cases approaching the rate of growth for the untreated roots. These facts are more clearly shown when values for each concentration are read from the smooth curves and plotted as percentage of control against time (hours after germination) as shown in figures 3A and 3B. It is ap-

parent that each of the concentrations inhibits root length maximally at the end of a given time (the percentage of inhibition increasing with increased concentration), after which time the inhibition falls off, each of the curves approaching the untreated control. When the time required to attain maximum inhibition is plotted against the logarithm of the concentration, the straight line plots shown in figure 4

are obtained (see data in table 2). The slopes of the two lines are 1.72 for Black Norway and 0.86 for Fulghum.

2. Root number.—The numbers of roots possessed by the two varieties at the end of 112, 158, and 230 hours after germination, when treated with various concentrations of 3-indole acetic acid, are shown in table 3. In this experiment the plants were removed from the filter paper at the end of 112 hours and placed in the glass holders used in the Avena test, the roots continuing their growth in tap water. It will be noted that at 112 hours in the controls, there seems to be little difference in the number of roots in the two varieties. After 230 hours, however, Fulghum possesses a considerably greater number of roots than Black Norway. Treatment with 3-indole acetic acid in both varieties has resulted after 230 hours in an increase in root number of about 100 per cent in the case of the highest concentrations used.

roots are shown in table 4 and are represented graphically in figures 5A and 5B. All concentrations used appear to stimulate shoot growth in Black Norway; the same concentrations, however, have little or no constant stimulatory or inhibitory effect in Fulghum. In order to ascertain whether the coleoptiles of the two varieties respond differently to 3-indole acetic acid applied directly, the standard Avena test was carried out using ten plants of each variety. The experiments on the curvature of the coleoptiles were carried out in a closed glass chamber in the darkroom in which the humidity was high and maintained at a constant level and in which the temperature varied between 23° and 25°C. The technique employed was the same as that described by Went and Thimann (1937) involving double decapitation. The test blocks placed asymmetrically on the coleoptile tips were prepared by soaking sections of 3 per cent agar for twelve hours in a 0.005 mg./l. solution of 3-indole acetic acid. Curvatures were recorded

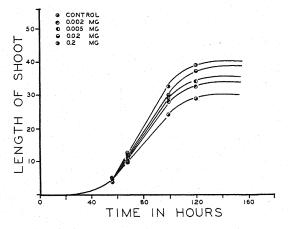

after two hours by the shadowgraph method. The average curvature of the test coleoptiles was 28.5° for Black Norway and 21.5° for Fulghum. A similar determination using a concentration of 0.002 mg./l. 3-indole acetic acid gave an average curvature of 11.1° for Black Norway and 8.9° for Fulghum.

Discussion.—The two oat varieties utilized in these experiments flower at different times of the year when grown in the field. The figures given below were placed at our disposal by Dr. G. M. Reed of the Brooklyn Botanic Garden:

Flowering time

	1929	1930
Black Norway	July 2 June 14	June 25 June 3

An examination of the average growth rates given above for Black Norway and Fulghum shows that there is an inverse relation between the time of flowering and rate of root growth—i.e., the slower the rate of root growth, the earlier the flowering time.

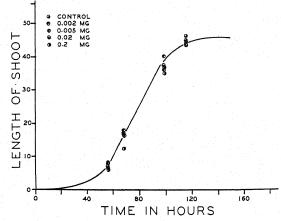

Fig. 5A (above). Effect of different concentrations of 3-indole acetic acid on the length of the shoot for Black Norway.

Fig. 5B (below). Effect of different concentrations of 3-indole acetic acid on the length of the shoot for Fulghum.

Such a relation has been verified for two other oat varieties, Victory and Navarro. If this relation is a general one, rate of early root growth may prove to be a valuable index of flowering time.

With respect to differences in response of roots to the same concentrations of 3-indole acetic acid, the data indicate that both varieties are inhibited to approximately the same degree; 60 per cent for both varieties with the lowest concentration used (0.01 mg./l.), 77 per cent and 74 per cent with a concentration of 0.05 mg./l., 82 per cent and 79 per cent with a concentration of 0.5 mg./l., and 90 per cent for both varieties with the highest concentration used (5.0 mg./l.). Although both varieties are maximally inhibited to the same extent, differences exist between them in the time at which maximum inhibition is obtained. With the exception of the lowest concentration, 0.01 mg./l., where Black Norway seems to recover from the effects of the treatment somewhat later than Fulghum (68 hours after germination in contrast to 66), the latter recovers later for the higher concentrations used.

The difference in the time at which recovery begins may best be expressed by the slopes of the two lines shown in figure 4. To put the results in a more simple form: the greater the slope (1.72 in contrast to 0.86), the more rapid the recovery from the applied 3-indole acetic acid. These results may be related to the earlier ones in the following way: the earlier the flowering time, the slower the rate of root growth, and the later the time at which maximum root inhibition (and consequently recovery) occurs when the roots are treated with 3-indole acetic acid. The fact that a straight line results when the data are plotted as indicated in figure 4 appears to offer a simple relationship between root inhibition and concentration of applied growth substance. This relationship may be simply expressed as follows: time (in hours after germination to attain maximum inhibition)  $\div$  log. concentration (in mg./l.) = K, where K is the slope of the line.

Such a method of plotting appears to rule out the undesirable elements in the methods previously used (I.ane, 1936; Marmer, 1937). Here, the inhibitory effects of applied 3-indole acetic acid were ascertained by determining the percentage of inhibition as compared with the untreated control at the end of a given time. When percentage of inhibition is plotted against the logarithm of the concentration, one obtains a relationship which is difficult to express in simple mathematical terms.

Thimann and Lane (1938) have shown that the effect of applied growth substance on root inhibition wears off after the seedlings have been transferred to water. Some of our early experiments clearly indicated that the effect of the growth substance falls off, whether or not the seedlings are transferred to water. Thus, when measurements of root length are made at one time, some roots may have already been maximally inhibited and others not. From this point of view, this method fails to evaluate comparable factors. In the present method, one is measuring in all cases apparently comparable factors, namely, the

times required for maximal inhibition. The K value computed on the basis of such data seems to be a valid criterion of sensitivity to applied growth substance. The disadvantage of this method consists in the need for a series of measurements rather than one set of measurements in order to derive the growth curves from which the necessary data are computed

It has been shown that the two varieties here studied differ in rate of early shoot growth and number of roots at the end of a certain time, as well as in rate of early root growth and flowering time. An initial higher auxin concentration with continued high auxin production in a variety like Fulghum might very well account, at least in part, for all the growth correlations cited above. Preliminary auxin determinations made by the authors on dry seeds, however, show that the initial auxin concentration of Black Norway is higher than that of Fulghum. Such an auxin differential might very well account for the fact that the root and shoot emerge first in Black Norway as compared to Fulghum. The faster rate of shoot growth, and the relatively slower rate of root growth, as well as the greater number of roots with time as exhibited by Fulghum can be reconciled only with the assumption that this variety produces auxin at a faster rate following germination. This assumption is strengthened by the following consideration. It has been shown (Skoog, 1937) that when young oat seedlings are deseeded, they become more sensitive to applied growth substance. This increase in sensitivity is believed to be due to a lack of auxin brought about by the removal of the seed. One would expect, therefore, that if a coleoptile of a plant normally possesses less auxin than another, it would be more sensitive to applied growth substance. In our experiments, Black Norway shows a greater sensitivity in the Avena test to 3-indole acetic acid applied in agar blocks.

Another group of data further strengthens the assumption that Fulghum produces more auxin than Black Norway. When the roots are treated with 3-indole acetic acid, the shoots of Black Norway are stimulated while those of Fulghum are relatively unaffected and appear to be inhibited by high concentrations. This may indicate that Black Norway is deficient in growth substance, the addition of which stimulates the growth of the shoot. Fulghum, on the other hand, is "satiated" with growth substance (Greenfield, 1937), the addition of which produces no stimulating effect. Or to put the results in another way: for Fulghum, there is sufficient growth substance, further addition producing no increased effect, since factors other than growth substance now become limiting in growth. For Black Norway, growth substance is still limiting; addition of growth substance produces acceleration until some other factor becomes limiting.

At the same time that shoots are being stimulated by applied growth substance in Black Norway, roots are being inhibited. Root length in Fulghum is also being inhibited while high concentrations of growth substance are inhibiting shoot growth. All concentrations reported upon (0.002 mg./l. to 50.0 mg./l. for a variety like Black Norway, which is assumed to produce auxin at a slower rate) have been found to inhibit root growth. Concentrations between 0.00004 mg./l. and 0.0002 mg./l., on the other hand, have been found by the authors to be stimulating up to about 15 per cent as compared with the controls. For roots, therefore, exceedingly low concentrations of growth substances are stimulating, higher concentrations inhibiting. Those concentrations which stimulate root growth produce no effect on shoot growth. Stimulation begins to be evident for Black Norway at concentrations of about 0.002 mg./l. and continue to about 2.0 mg./l., after which further increases bring about inhibition. No such stimulatory effect is apparent in a variety like Fulghum.

With respect to number of roots, a higher rate of auxin production is again indicated in a variety like Fulghum since this variety possesses a larger number of roots at the end of 230 hours than Black Norway. For root number, however, auxin has not become limiting for both varieties, so that further addition of growth substance up to as much as 50.0

mg./l. continues to produce an increase.

All the above facts, therefore, point to a difference in auxin production between Fulghum and Black Norway. Furthermore, this difference is sufficient to account at least in part for all the correlations pointed out above with respect to root and shoot growth as well as root number. These results appear to support Thimann's (1937) view that plant parts respond to auxin in essentially the same way, except that they differ in their sensitivity to it.

Detailed experiments have already been undertaken to test the assumptions outlined above.

### SUMMARY

A simple method is described for carrying out growth measurements on oat seedlings over a period of four to five days.

Differences in early root and shoot growth (in the absence of light) are described for two varieties of Avena sativa. Black Norway, a late flowering variety, shows a more rapid root growth and a slower shoot growth than Fulghum, an early flowering variety.

The roots of these two varieties, when treated with aqueous solutions of 3-indole acetic acid ranging in concentration between 0.01 mg./l. and 5.0 mg./l., show the same maximum inhibition. The time at which maximum inhibition occurs is essentially the same in both varieties at low concentrations, but is later for Fulghum than for Black Norway at higher concentrations.

There is a direct relationship between the time at which maximum inhibition occurs and the logarithm of the concentration of 3-indole acetic acid used. The straight line plots have markedly different

slopes in the two varieties.

Concentrations of 3-indole acetic acid up to 50.0 mg./l. increase root number in both varieties in a similar manner. Low concentrations (0.002 mg./l. or less) are relatively ineffective in stimulating root formation, the effect being more pronounced with higher concentrations.

The two varieties differ in the effect on early shoot growth of 3-indole acetic acid applied in solution through the roots. Black Norway shoots show more rapid growth when treated with concentrations between 0.002 mg./l. and 2.0 mg./l., while Fulghum shoots remain unaffected. In addition, the coleoptiles respond differently in the *Avena* test, Black Norway appearing to be more sensitive.

The above results are interpreted in part on the basis of an assumption that Fulghum normally produces auxin at a faster rate than Black Norway.

# THE DAILY CYCLE OF APPARENT PHOTOSYNTHESIS IN A SUBMERGED AQUATIC $^{\scriptscriptstyle 1}$

Bernard S. Meyer

The daily cycle of apparent photosynthesis in terrestrial species, under conditions approximating those which such plants encounter in nature, has been studied by Kostychev et al. (1926, 1928), Beljakoff (1928), Thomas and Hill (1937), and others. Such investigations have contributed to an understanding of the fundamental physiology and the ecological behavior of a number of species of plants. The results of two such investigations upon submerged vascular plants are also recorded in the literature.

Kostychev and Soldatenkow (1926) studied the daily variations in the rate of photosynthesis in a number of species of algae and submerged vascular aquatics. Apparent photosynthesis was measured in terms of oxygen evolution, which was determined by the Winkler method. In general their results seemed to indicate attainment of a maximum rate of photosynthesis in the mid-portion of the day, but most frequently before noon, and a usually consistent decrease in rate thereafter. The frequently found skewing of the curves toward the morning hours was attributed to the limiting effect of some internal factor, probably the accumulation of the products of photosynthesis.

A paper by Gessner (1938), part of which is devoted to a consideration of the daily cycle of photosynthesis in a number of species of submerged vascular aquatics, appeared after the experimental portion of this investigation was completed. Gessner employed a method which, in general, was similar to that used by Kostychev and Soldatenkow, except for modifications which eliminated or greatly reduced certain experimental errors present in their work. Plants were enclosed in 600 ml. glass flasks in water of reduced and known oxygen content and exposed to light while held in a horizontal position just under the surface of the water in a large pool. At the end of each hour, or in some experiments each half hour, the plant was transferred to another flask full of the water of low oxygen content, and the water from which the plant had been removed titrated for oxygen content by the Winkler method. Apparent photosynthesis was expressed in terms of oxygen evolution per hour. In general, Gessner found the daily curve of photosynthesis in submerged vascular aquatics to be closely correlated with the daily curve of radiation intensity.

The object of the investigation reported in this paper was the determination of the daily cycle of apparent photosynthesis in a representative submerged vascular aquatic species—Ceratophyllum demersum L.—under the most favorable light, bicarbonate concentration, and temperature conditions likely to be

1 Received for publication June 9, 1939.

Papers from the Franz Theodore Stone Laboratory and the Department of Botany, No. 410, of the Ohio State University. encountered by this species as it grows naturally in Lake Erie. Hence, only results obtained on clear days are reported. The experimental method employed was such that the rate of apparent photosynthesis could be determined for hourly intervals for a daily period of illumination without disturbing or handling the plant in any way.

EXPERIMENTAL PROCEDURE.—The apparatus employed incorporated some of the features of the experimental set-ups of Blackman and Smith (1911) and James (1928). In brief, the method consists in enclosing the plant to be studied in a glass chamber, circulating a solution of known and constant, but relatively low, oxygen content through this chamber, collecting the effluent stream of solution in a suitable pipette and determining its oxygen content. The rate of apparent photosynthesis<sup>2</sup> is calculated from the gain in the oxygen content of the water which has circulated through the plant chamber.

With the exception of the plant chamber, the water bath in which it was immersed, and the connecting tubes, the entire apparatus (fig. 1) was arranged on a table just inside a south-facing window of the laboratory. A tinned metal drum (A) of about 35 liters capacity, heavily coated with paraffin on the inside, was used as a reservoir for the affluent solution. The reservoir was provided with a round, snug-fitting float of paraffin about 1 cm. in thickness.

<sup>2</sup> The term "apparent photosynthesis" is used in the sense of photosynthesis minus respiration.

<sup>3</sup> The terms "effluent" and "affluent" are used with respect to the plant chamber.

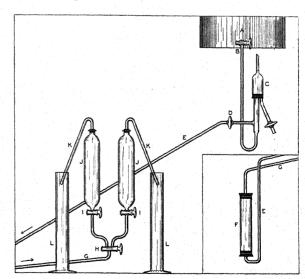

Fig. 1. Apparatus for the determination of photosynthesis in submerged water plants. A, reservoir; B, D, H, II, stopcocks; C, constant level device; E, G, glass tubes; F, plant chamber; IJ, pipettes; KK, overflow tubes; LL, graduated cylinders.

This served to prevent solution of atmospheric oxygen in the solution of low oxygen content in the reservoir. The reservoir was provided, on opposite sides at the bottom, with two glass stopcocks inserted through rubber stoppers. One of these (not shown in the figure) was used to obtain samples for testing the oxygen content of the solution in the reservoir. The other (B) was connected to a constant level device (C). From this device the affluent stream of solution passed through stopcock D and the downward slanting glass tube E out through the adjacent window to the plant chamber.

A glass cylinder, 4 cm. in inside diameter and 20 cm. in height was used as the plant chamber F (insert of fig. 1). This was fastened in position and immersed in the water contained in a large galvanized iron tub (diameter about 75 cm.; depth about 40 cm.). This tub was blackened on the inside and served as a water bath. It was supported on a low table a short distance outside the laboratory window. The temperature of the water bath was maintained nearly constant by a continuous flow of lake water which entered through a hose and escaped by overflowing the rim of the tub.

The glass cylinder which was employed as a plant chamber was stoppered, top and bottom, with tight-fitting rubber stoppers. The affluent stream of solution entered through the glass tube E which was tapped into the bottom stopper. The effluent stream left through the glass tube G which was inserted into the upper stopper. The effluent stream from the plant chamber passed through the glass tube G back into the laboratory to the three-way stopcock H which in turn was connected with the two cylindrical 700 ml. pipettes, J, J.

The passage of the stream of solution through the entire system is brought about by the hydrostatic pressure resulting from the difference in elevation of the top of the water column in the constant level device and the lower ends of the overflow tubes K, K. The arrangement of the apparatus is such that the circulating solution moves "uphill" from the bottom of the plant chamber to the top of the pipette. This facilitates clearing out any air bubbles which become entrained in the apparatus while it is being prepared for an experimental run. The stoppers at the top of the plant chamber and at the top of the pipettes were hollowed on the bottom in order to prevent air bubbles being entrained at those points when they were carried through the apparatus.

Although the hornwort is a rooted submerged aquatic, the apical portions of the plants, which are the most active photosynthetically, are commonly located just under the surface of the water. The apical portions of healthy, vigorous plants were collected directly from open water in shallow portions of Lake Erie the evening before a determination started and kept in a large jar of lake water overnight.

About one hour prior to the beginning of a determination approximately 16 liters of distilled water, with an oxygen content about half that of water in equilibrium with the partial pressure of oxygen in

the atmosphere at the same temperature, were introduced into the reservoir. Reduction in the oxygen content of the water was effected by boiling sufficient quantities in 6-liter Pyrex flasks and cooling to room temperature with the neck of the flask blocked with a snug-fitting float so that atmospheric oxygen did not have free access to the water. The water was boiled and cooled the day prior to running the experiment.

Sufficient sodium bicarbonate to bring the concentration of the final volume of solution to 0.02 per cent was dissolved in a small quantity of distilled water and quickly but thoroughly stirred into the water in the reservoir. The paraffin float was then placed in position on top of the solution.

The upper stopper of the plant chamber was then removed and the entire apparatus to the top of the plant chamber was filled with fresh solution. The apical 15 cm. (approximately) was cut from a suitable plant, a small glass weight tied to its basal end, and the plant inserted in the plant chamber, in which it assumed an approximately vertical position similar to its usual orientation in nature.

The upper stopper of the plant chamber was then inserted in position and both stoppers tightly wired in place. Since the top of the plant was about 5 cm. below the upper stopper, and since the tube was slanted slightly away from the direction of the noonday sun, the plant was at no time during the day in the shadow of the upper stopper.

The solution was then allowed to flow rapidly through the apparatus while connected to an empty pipette until the entire system was cleared of air bubbles. As soon as this was accomplished, flow was adjusted to the standard rate of about 800 ml. per hour. This rate of flow was maintained through the apparatus for at least half an hour before the beginning of the experimental run in order to allow the plant to attain a dynamic equilibrium with the solution.

Each daily series of determinations was begun at 5:30 or 6:30 a.m. At this time the effluent stream of solution from the plant chamber was switched through stopcock H to the other pipette, which had previously been filled with a solution of methylene blue in 10 per cent ethyl alcohol. The rate of solution flow was readjusted to 800 ml. per hour by proper manipulation of stopcocks B, D, and I.

The entering solution gradually displaced the methylene blue solution from the pipette through the overflow tube K into the glass graduate L. The rate of flow was checked at approximately 10-minute intervals, being followed closely by the rise in level of the liquid in the graduated glass cylinder. The exact flow was determined at the end of each hour by weighing the water which had been displaced into the graduate.

Because of its lower density the methylene blue solution floats as a distinct layer above the entering water. A sharp interface is maintained between the two layers of liquid. Interchange by mixing between the two liquids therefore does not occur, and any exchanges which occur by diffusion are probably small.

At the end of an hour all the methylene blue solution has been displaced from the pipette and about 100 ml. of the effluent solution has also overflowed into the graduated cylinder. At the end of each hour's run the effluent stream of solution is switched to the other pipette, which in the meantime has been filled with fresh methylene blue solution.

The purpose of the methylene blue solution was twofold: (1) to prevent direct contact of the effluent solution with the atmospheric oxygen and (2) to prevent a sudden change in the effective hydrostatic pressure which would ensue if the effluent solution were switched to an empty pipette at the end of each hour.

Duplicate 100 ml. aliquots of the solution in the pipette and of the solution in the reservoir were withdrawn at the end of each hour, suitable precautions being taken to avoid contact of the solutions with the atmosphere. The samples were analyzed for oxygen by the Winkler method, following with slight modifications the method as outlined in Theroux, et al. (1936). For a recent evaluation of this method for use in biological work see Allee and Oesting (1934).

The volume of oxygen liberated from the plant during each one-hour period was computed by multiplying the excess oxygen content of 100 ml. of solution from the pipette over that in 100 ml. of solution from the reservoir by the number of 100 ml. units (approximately 8) of water which entered the pipette during that hour. The rate of oxygen evolution was used as an index of the rate of apparent

photosynthesis.

The oxygen content of the solution in the reservoir usually showed a small rise during the day, probably due to a slight leakage at the edge of the paraffin float. This increase never amounted to more than 5 per cent of the amount originally present. For any given hourly interval, however, the oxygen content of the solution entering the plant chamber

was virtually constant.

As is well known, bubbles of gas containing a large proportion of oxygen often escape from submerged aquatic plants when illuminated. The more nearly static the water surrounding the plants and the more nearly saturated it is with respect to the partial pressure of oxygen in the intercellular spaces, the more likely gas bubbles are to escape from the plants. Obviously if any escape of oxygen occurred from the plants in gaseous form during these experiments, the results would be invalidated, as the method employed provides only for the analysis of dissolved oxygen. The procedure followed, however (that of immersing the plants in a continuously flowing stream of water of relatively low oxygen content) obviated this difficulty, and emission of bubbles did not occur at any time from the plants while they were being used in the experiments reported in this paper.

RESULTS AND DISCUSSION.—The results of four determinations of the daily cycle of apparent photosynthesis in *Ceratophyllum demersum* are shown graphically in figure 2. The number on each curve

corresponds to the day in August, 1937, on which the determination was made. For convenience these numbers will be used to refer to the individual curves.

As shown in this figure, the rate of apparent photosynthesis rose rapidly during the early morning hours to a peak value which was attained in the Au-

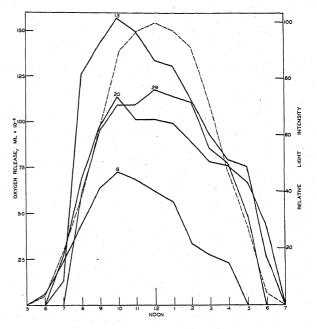

Fig. 2. Daily cycle of apparent photosynthesis in *Ceratophyllum demersum* on August 8, 13, 20, and 29, 1937 (solid lines). Daily variation in horizontal component of solar radiation on August 13, 1937 (broken line).

gust 29 curve at 12 noon, and in the other curves at 10:00 a.m. In general, after the peak rate had once been attained the rate of apparent photosynthesis declined consistently during the rest of the day, falling to a zero value by late afternoon. Actually, during the hours which are designated with a zero value for oxygen release, consumption of oxygen was occurring in the process of respiration.

In general the curves show a fairly close correlation with the daily cycle of solar radiation on a clear day, except that most of them are skewed toward the morning hours. This skewing is particularly marked in curves 8 and 13 and is also apparent in curve 20. Curve 29, on the other hand, is essentially symmetrical with a peak rate of apparent photosynthesis during the midday hour. Of four other similar determinations made during July and August, 1937, two give clear indications of a maximum of apparent photosynthesis before noon, and two give clear indications of a fairly symmetrical curve of apparent photosynthesis with the peak value at noon. The curves for these experiments are not reproduced because recognized experimental errors or temporary

<sup>4</sup> In figure 2 the figure 10 on the abscissa represents the hour from 9:30 to 10:30, etc. The time as given is true solar time.

periods of cloudiness invalidated one or more of the hourly determinations.

The possible rôle of each of the factors which may have influenced the daily cycle of photosynthesis in these experiments will now be considered.

Light.—The arrangement of the plant in the plant chamber was such that the radiant energy impinging upon it could not have differed materially from that received by similar plants growing at the same depth below the surface of the lake in clear, quiet water, under the same conditions of solar radiation. The quality and intensity of the light incident upon the plant were modified only slightly by its passage through the walls of the glass chamber, since the coefficient of light absorption for thin layers of glass is very low.

With certain minor exceptions, to be noted shortly, the plants were exposed to the daily cycle of solar radiation as it prevails on clear August days throughout each of the experiments. Hourly determinations of the horizontal component of solar radiation were made during each experiment with a Weston "Photronic" cell connected to a suitable milliammeter. Although such photovoltaic cells have definite limitations as instruments for measuring solar radiation, results obtained with them have at least a roughly quantitative significance. The curve of relative light intensity for August 13 is shown in figure 2. A subsequent checking of the photocell used against a calibrated pyrheliometer showed the peak value for solar radiation on this day to be about 1.25 g.-cal./cm.2/min., corresponding to an illumination value of about 8,500 foot candles. The daily cycles of intensity of solar radiation on August 8 and August 20 were closely similar to that for August 13, except that a severe thunderstorm greatly reduced the light intensity after 4:00 p.m. on August 8. On August 29 the intensity of solar radiation was slightly less (about 10-15 per cent) at all hours than on the other three days.

A correlation of the rate of apparent photosynthesis with light intensity is well marked in all the curves during the morning hours, and in some is also apparent for the afternoon hours. It is evident that the light intensity incident on a given leaf must attain a certain value if a maximum rate of photosynthesis is to be attained by that leaf under the other environmental factors prevailing. At light intensities above this value, light will no longer be the limiting factor in photosynthesis. This "optimum" light intensity is probably approximately the same for all the leaves on a given shoot. Hence, if all the leaves on a shoot are directly illuminated, an increase in the rate of photosynthesis should occur up to this "optimum," beyond which there will be no further increase with increase in light intensity. Such however, is not the situation. All the apical portions of the plants used consisted of one main branch to which were attached several shorter lateral branches. Because of this fact and the fact that the branches were densely clothed with leaves, some shading of interior by exterior leaves necessarily oc-

curred. Increase in light intensity will increase the incidence of light on all the leaves, but the exterior ones will be consistently exposed to a stronger light than the interior leaves. Hence, when the outer leaves are receiving light of "optimum" intensity, the incidence of light on inner shaded leaves may be much less.

It has been shown for a number of species of plants that the "optimum" light intensity for photosynthesis per leaf is less than the maximum possible solar illumination and this is undoubtedly also true of the hornwort. Because of the shaded condition of many interior leaves the rate of photosynthesis per shoot will increase with increase in the intensity of sunlight much beyond the optimum intensity for photosynthesis in a leaf which is fully exposed to radiation. The higher the intensity of solar radiation, the higher the average incidence of light on the leaves. The larger the proportion of the leaf surface which is sufficiently illuminated that light is no longer the limiting factor, the greater the rate of photosynthesis per shoot. The observed close correlation of photosynthetic rates with light intensity during all or part of the day probably can be largely ascribed to this effect. That shading of inner leaves by those at the periphery of the plant is an important factor in determining photosynthetic rates per plant in land species has been shown by Heinecke and Childers (1937), and it seems probable that this same effect also operates in submerged aquatics.

The possibility that the decrease in rate of apparent photosynthesis which was often observed in these experiments before the maximum of solar radiation was attained might be due to a retarding effect of high light intensities should be evaluated. According to Ruttner (1926), Schomer (1934), and others, when vascular aquatics are submerged at different depths in a body of water, the maximum rate of apparent photosynthesis often occurs at some distance below the surface rather than just under the surface. Similar results have been obtained by several investigators with algae. Since, however, both the quality and intensity of light change with its depth of penetration into water, the results of these experiments cannot be ascribed unequivocably to a retarding effect of high light intensities upon photosynthesis.

Arnold (1931) found the rate of photosynthesis of submerged aquatics to diminish with time when exposed to strong light under supposedly constant environmental conditions. This conclusion, however, is contradicted by the experimental work of Emerson (1935) and Gessner (1938). The results of the latter investigator indicate very convincingly that high light intensities (80,000–130,000 lux) per se do not exert a retarding effect upon photosynthesis in a number of species of submerged vascular aquatics including Ceratophyllum. Arnold's results, as is clearly pointed out by Gessner, can be ascribed to the use of a bubble-counting technique for measuring photosynthesis which is inherently unsuitable for use in such an investigation. It seems certain,

therefore, that the shape of the curves of apparent photosynthesis as obtained in this investigation cannot be accounted for by a retarding effect of high

light intensities upon photosynthesis.

Neither does it seem probable that high light intensities could exert an accelerating effect on respiration which would result in a diminution in the rate of apparent photosynthesis, since there is considerable evidence that light exerts no direct effect upon respiration (see, for example, McAlister, 1939).

Bicarbonate concentration of the water.—A 0.02 per cent solution of sodium bicarbonate (NaHCO<sub>3</sub>) was used in all experiments. The free carbon dioxide content of Lake Erie water, as would be expected from its pH value (approximately 8.0 in the summer), is negligible. The carbonate content of the waters of western Lake Erie, in terms of calcium carbonate, is about 90 parts per million during the summer months. Only a very small proportion of this (less than 5 per cent) represents carbonates, the remainder being in the form of bicarbonates. The calcium ion is present in Lake Erie water in a far greater concentration than any other cation, so there is no doubt that Ca(HCO<sub>3</sub>)<sub>2</sub> is the principal source of carbon dioxide for aquatic plants in this

Since one part by weight of NaHCO3 is equivalent to 1.19 parts of CaCO<sub>3</sub>, the bicarbonate concentration of the solution used was slightly more than twice as great as the usual values for western Lake Erie waters. This higher bicarbonate concentration was deliberately chosen because it was desired to have conditions in these experiments correspond to the most favorable conditions which ever prevail for photosynthesis in Lake Erie, and it is considered possible that higher bicarbonate concentrations than those reported above may sometimes exist in the lake.

It is obvious from the shape of the resulting curves that the bicarbonate concentration of the solution could not have been a limiting factor in photosynthesis for the entire shoot as a unit, except

possibly when peak values were obtained.

Oxygen content.—The oxygen content of the solutions entering the plant chamber was only about one-half that of saturated6 water at the same temperature. The water from the shallower portions of western Lake Erie is usually approximately saturated with oxygen. The oxygen content of the solutions used in these experiments was therefore considerably less than that encountered by submerged aquatics under natural conditions in this region. Actually the oxygen content of the water in the plant chamber often considerably exceeded that of the water entering from the reservoir due to the evolution of oxygen in photosynthesis.

<sup>5</sup> The figures quoted in this paragraph are based on

analyses by Mr. Leonard Bodenlos.

<sup>6</sup> In this paper the term "saturated" is used to describe solutions in which the oxygen content is in equilibrium with the partial pressure of the oxygen in the atmosphere at the same temperature.

There are no valid grounds for believing that variations in the oxygen content of the solutions of the magnitude which occured in these experiments have any appreciable effects upon the rates of either photosynthesis or respiration. Although there is some evidence that oxygen is necessary for photosynthesis, all available data indicate that only a very great reduction in the oxygen concentration of an air or water environment has any appreciable effect on this process. Likewise a diminution in the oxygen content of water has little effect on the rate of respiration unless it is very marked. Gessner (1937), for example, has shown for several submerged aquatic species that the oxygen content of the water must be reduced to 20 per cent of the saturation value or less before the rate of respiration is appreciably influenced.

Rate of flow of the solution.—The rate of flow through the plant chamber (volume about 200 ml.) in these experiments was 800  $\pm$  25 ml. per hour and was hence equivalent to approximately four complete changes of the water in the plant chamber per. hour. This rate was necessarily chosen somewhat arbitrarily, but equivalent natural agitation of the water is undoubtedly of frequent occurrence in Lake Erie. The rate of change of solution in the plant chamber was sufficiently rapid to obviate any appre-

ciable lag effect in the apparatus.

Temperature.—Since the plant chamber was immersed in a tub through which lake water was circulated rapidly, its temperature, as indicated by a thermometer inserted through the upper stopper (not shown in fig. 1), did not deviate greatly from that of the lake water. The temperature of the water in the plant chamber was  $26 \pm 1$  °C. in experiments 8, 13, and 29, and  $27 \pm 1$  °C. in experiment 20. These correspond approximately to the highest temperatures attained by Lake Erie water in the island region during the summer months. As a result of direct insolation effects on the water bath the temperature of the plant chamber was always slightly higher (1-2°C.) during the afternoon hours than during the morning hours.

It is evident from the shape of the curves in figure 2 that temperature could not have been the limiting factor in determining rates of photosynthesis in these experiments except possibly when peak rates were attained. Particularly it should be noted that the frequently observed skewing of the curves toward the morning hours cannot be ascribed to the temperature factor. It might be argued that the slightly higher afternoon temperatures induced a proportionately greater rise in the rate of respiration than in the rate of photosynthesis, thus causing a decrease in the rate of apparent photosynthesis. The fact that the rate of apparent photosynthesis often began to decrease by 10 o'clock in the morning renders such an explanation untenable.

Internal factors.—Since the frequently observed skewing of the curves of apparent photosynthesis cannot clearly be traced to any one or a combination of environmental factors, the possibility that this

effect may be due to the operation of some internal factor should be considered. One such factor is the accumulation of the products of the photosynthesis, which, according to Kostychev et al. (1926), Tschesnokov and Bazyrina (1930), Kurssanow (1933), and others, exerts a retarding effect upon photosynthesis in terrestrial species. Under certain conditions, as a result of the effect of this factor, the peak rate of photosynthesis may occur before noon.

Kostychev and Soldatenkow (1926) claim to have demonstrated such an effect of the accumulation of the products of photosynthesis in submerged aquatic species, but their experimental procedure is open to considerable criticism. Gessner (1938), on the other hand, considers that there is no basis for believing that the daily course of apparent photosynthesis in submerged aquatics is appreciably influenced by internal factors.

As far as the results of the present investigation go, at least a possibility that the daily course of photosynthesis is influenced by internal factors must be recognized. The fact that the frequently observed skewing of the daily curves of photosynthesis toward the morning hours cannot be traced to the influence of any environmental factor suggests that some internal factor—quite plausibly the accumulation of photosynthetic products—may often be exerting a limiting effect, especially during the afternoon hours. The existence of such a factor or factors, however, has not been experimentally confirmed.

#### SUMMARY

An apparatus is described with which it is possible to make consecutive hourly determinations of the rate of apparent photosynthesis in a submerged aquatic without disturbing or handling the plant in any way during the course of an experiment. On clear days in late July and in August with the temperature of the water in which the plant is immersed showing only a slight daily variation, the rate of apparent photosynthesis in apical shoots of Ceratophyllum demersum L. shows a rapid rise during the morning hours to a peak value which is attained between 10 a.m. and 12 noon, after which it shows a consistent decline. In general the daily curve for apparent photosynthesis shows a close correlation with the daily curve for the intensity of solar radiation, especially during the morning hours. Variations in light intensity are undoubtedly the principal factor involved in changes in the magnitude of apparent photosynthesis in this species from hour to hour throughout the day. The frequently observed skewing of the curves of apparent photosynthesis toward the morning hours, which apparently cannot be attributed to any environmental factor, suggests the possibility that an internal factor or factors may also exert an influence on the daily course of photosynthesis in this species.

# CYTOPLASMIC INCLUSIONS IN THE MALE GAMETES OF LILIUM 1

Lewis E. Anderson

THE RESULTS of several investigations conducted during the past few years indicate that the male gametes in a number of angiosperms are complete cells. According to these workers, a distinct zone of cytoplasm surrounds the male nucleus during its passage down the pollen tube, and a few workers have described cellular male gametes in the embryo sac. The subsequent entrance of the male cell into the egg has not been observed, but it is conceivable that the entire cell may enter the egg. Thus, male cytoplasm would be introduced into the egg during fertilization. Little is known concerning the cytoplasm of male gametes, and no one has demonstrated the presence or absence of cytoplasmic inclusions. It seemed of interest, therefore, to study the gametes of Lilium, which have been shown to be cells by Cooper (1936), to see if they contain inclusions similar to those which have been described as occurring in the vegetative cells of the pollen tubes of many other plants.

Nicolosi-Roncati (1910), and more recently Wagner (1927), observed mitochondria during reductional division in *Helleborus foetidus* and found that they were about equally distributed among the resulting microspores. Similar observations have been made by Lewitsky (1911) on *Asparagus*, Bonnet (1912) on *Cobea*, Guilliermond (1912) on certain cucurbits and *Lilium* (1924), Wóycicki (1923) on *Malva*, Noack (1921) on *Pelargonium*, Dangeard (1922) on *Iris*, and Anderson (1936) on *Hyacin*-

thus.

Plastids and mitochondria are generally known to be almost universally present in the vegetative cell of pollen grains of angiosperms. In some plants the elaboration of starch by plastids in the pollen grains is assumed to furnish food for the growth of the pollen tube. Less is known, however, concerning the cytoplasm of the generative cell. Ruhland and Wetzel (1924) described plastids in recently formed generative cells of Lupinus, but they found that the plastids gradually disappear as the generative cell passes down the pollen tube. These authors asserted that chondriosomal bodies in the older generative cells originate from the evanescent plastids. Guilliermond (1924), on the other hand, was unable to demonstrate starch at any time in the generative cells of Lilium, but he found starch to be abundant in the vegetative cell. Anderson (1936) found abundant mitochondria and plastids in the pollen tubes of Hyacinthus and Antirrhinum and observed that

<sup>1</sup> Received for publication August 17, 1939.

This study was aided by a grant from the Research Council of Duke University. A portion of the work was done at the University of Wisconsin during the summer of 1938. The writer is indebted to Professor C. E. Allen for many helpful suggestions and criticisms and to Dr. D. C. Cooper for information concerning the growth of pollen tubes.

these inclusions are especially aggregated around the male gametes. Nothing is known, however, concerning the inclusions in the gametes themselves.

MATERIAL AND METHODS.—Three species of Lilium were used in the present study—L. regale Wils., L. tigrinum Ker., and L. philippinense Baker. The plants were grown on the campus of the University of Wisconsin and in the greenhouse of Duke University. Pollinations were carried on during the summer of 1938 at the University of Wisconsin and during the winter of 1938-39 at Duke University.

Pellen tubes were obtained for study by germinating pollen both artificially and naturally. For natural germination, stigmas were pollinated and the stigma and style removed at intervals between 24 and 72 hours. In some instances the entire style and stigma was fixed for 12 to 24 hours, embedded in paraffin, sectioned longitudinally, and stained in Heidenhain's iron-alum haematoxylin. In others, the styles were slit longitudinally, the pollen tubes carefully removed, placed on a slide, fixed for one to two hours, stained, and mounted whole in canada balsam. Although satisfactory preparations were obtained by the latter method, it was necessary to handle the tubes with great care during the process of dehydration and staining to prevent them from twisting and stretching. When proper precautions were taken, however, tubes were obtained which compared favorably with those sectioned in the style. Cytoplasmic inclusions are more easily stained in pollen tubes which have been sectioned thinly, but they are unfavorable for study, since a section rarely extends very far through a given pollen tube.

The most satisfactory pollen tubes were obtained by germinating the pollen grains on slides which had been smeared with stigmatic exudate, according to the method described by Cooper (1936). The stigmatic exudate, which is produced freely in Lilium, was smeared on a chemically clean slide and the pollen dusted thereon. The slides were placed in a moist chamber and allowed to remain for 48 to 72 hours; they were then fixed for 1 to 2 hours, stained in iron-alum haematoxylin, and mounted whole in balsam. Some workers have criticized this method, stating that pollen tubes grown in this manner are abnormal, but no differences other than in size could be noted between pollen tubes grown in culture and those grown in the styles. Tubes grown in culture average considerably larger than those grown in the styles. This can be partially accounted for by the fact that those from the styles are shrunken somewhat because of the slow penetration of the fixing fluid.

A variety of fixing fluids were used. For stages where division figures were desired, several chromosmic mixtures were employed. The most satisfactory of these were Benda's, with and without acetic,

Bensley's, and Regaud's fixatives. These gave good results with pollen tubes which had been grown on slides and were as a consequence directly exposed to the action of the fixing fluid. Since they penetrate very slowly, these fixatives were less satisfactory when entire styles were fixed. Where division figures were not desired, Zirkle's modification of Erliki's fixative (without pyridine) was used. This fixative produces a typical basic image. The chromatin is dissolved, and the nucleus is preserved as a solid mass of precipitated nuclear lymph. All figures, with the exception of figure 2, were drawn from pollen tubes fixed in this fluid. Figure 2 was drawn from material which had been fixed in Benda's fluid.

OBSERVATIONS.—The confusion of terms used to designate cytoplasmic inclusions necessitates a definition of those employed in the present paper. Most cytologists agree that plastids originate from visible primordia in the cytoplasm. Some maintain that plastid primordia and mitochondria are separate and distinct bodies, but thus far attempts to distinguish between them by means of stains, size, shape, etc., have failed. Sorokin (1938) reported that Janus Green B stains mitochondria when exact control of pH is maintained, but not plastid primordia. Attempts of the writer, however, to distinguish between plastid primordia and mitochondria in pollen tubes of Lilium with the use of Janus Green B were unsuccessful. Some inclusions are colored by the dve and others are not, as Sorokin observed, but there is no evidence that the unstained inclusions are the primordia of plastids. The inclusions which stain with Janus Green B are morphologically similar to those which do not stain, and it has not been demonstrated that Janus Green B shows any specificity for mitochondria in plants. For convenience, therefore, the term "mitochondria" will be used to include the primordia of plastids. The term plastid is reserved for those bodies containing starch.

The abundant inclusions in the pollen grains of Lilium are crowded in the cytoplasm between numerous and regularly arranged vacuoles. Guilliermond (1920) described a similar vacuolar system in L. candidum, and Anderson (1936) found the same condition in certain other plants with large pollen grains. Although the vegetative cell of the pollen grain is almost filled with oil globules, numerous mitochondria and plastids occur as well. These have been adequately described in vegetative cells of other plants (Guilliermond, 1924; Anderson, 1936).

The generative cell in ungerminated pollen grains is a complete cell, bounded by a distinct membrane which separates its cytoplasm from that of the vegetative cell. Starch is lacking at the time the pollen is mature, although Guilliermond (l.c.) described starch and plastids in the generative cell during earlier stages. Mitochondria are present in abundance throughout the cytoplasm, but they are especially aggregated around the elongated nucleus. Mitochondria are in the form of solid spheres and rods. A few are thread-like, and many are variously curved.

Many hollow spheres occur, as well as rods which are vacuolate at one or both ends. There is no evidence of plastids in the generative cell at any stage of its development. Guilliermond (1924) found starch in the generative cells of *L. candidum* immediately after they are formed, but concluded that starch, and consequently the plastids, soon disappears following pollination.

Shortly after the pollen grain germinates, the generative cell and tube nucleus pass into the pollen tube. The tube nucleus usually precedes the generative cell (fig. 4), but sometimes the generative cell enters first. If the latter occurs, the tube nucleus passes the generative cell after a short time. The tube nucleus varies in shape, size, and staining reaction. In most instances it is considerably larger than the generative nucleus and is globular or pearshaped (fig. 4). Sometimes, however, it is elongated, appearing almost thread-like. This appearance may be caused by poor fixation or by the beginning of its disintegration. The tube nucleus is always free in the cytoplasm of the pollen tube, and frequently cytoplasmic inclusions are massed around its periphery.

The cytoplasm of the generative cell is bound by a distinct membrane, which separates it from the cytoplasm of the vegetative cell (fig. 1, 2, 5). Although the nature of this membrane was not studied, its presence can be easily demonstrated in fixed material. The membrane is particularly evident when there is excessive shrinkage following fixation and dehydration, for then the generative cell is completely separated from the cytoplasm of the pollen tube (fig. 1). Most preparations show this space around the generative cell to a greater or lesser extent, but in some preparations it is absent (fig. 5). There is no evidence that the membrane is other than a cytoplasmic one.

Vacuoles are present in the cytoplasm of some generative cells and almost entirely absent in others. Cells which are exceedingly long and attenuated lack vacuoles (fig. 5). Generative cells, on the other hand, which are short and thick usually exhibit numerous vacuoles scattered throughout their cytoplasm (fig. 1). Mitochondria are exceedingly abundant. They are preserved in the form of solid and hollow spheres, straight and curved rods, and chains. Plastids are altogether lacking, although the characteristic stages, intermediate between mitochondria and plastids, are present (fig. 1, 5).

The division of the generative cell occurs 48 to 72 hours after pollen germination. Nuclear division has been described in detail by Cooper (1936), who reported the division as normal in every respect. The prophases are of long duration, the spireme being initiated shortly after the pollen tube is formed. During the prophase mitochondria are grouped abundantly around the nuclear membrane, and when the nuclear membrane disappears just prior to the formation of the equatorial plate, inclusions are scattered throughout the region of the spindle. Spindle fibers were not observed, but Cooper (1936) de-

scribed a typical spindle in *L. regale*, *L. auratum*, and *L. philippinense*. The chromosomes at metaphase are exceedingly long, and after the halves separate, a single chromosome may extend for half the length of the generative cell. The separation of the chromosomes and their movement to the poles during anaphase is normal (fig. 2). In some generative cells, which have become exceedingly long and narrow, the chromosomes are crowded together and occupy almost the entire central region of the cell. Mitochondria and other inclusions in such cells are mostly confined to the extremities, but they may be so numerous that they clump together in a solid, dark-staining mass which may completely occupy the attenuated ends of the generative cell.

After the chromosomes separate at metaphase and pass to the poles, mitochondria are often present in the region of the equatorial plate (fig. 2). Cell plate formation, and the subsequent division of the cytoplasm to form the two male gametes, evidently takes place rapidly. The details of the formation of the cell plate and the formation of the two gametes, were not followed, for Cooper (1936) described this process in detail. When the cytoplasm divides, inclusions are incorporated into each of the resulting

male gametes (fig. 7).

The male gametes are complete cells (fig. 3, 7) as soon as they are formed, having derived their cytoplasm and inclusions from the generative cell. The two gametes soon separate (fig. 3), and each contains abundant mitochondria. There are no connecting strands of cytoplasm between the gametes as have been reported in Vallisneria (Wylie, 1923) and Oenothera (Ishikawa, 1918). Each gamete is completely independent of the other. The gametes remain independent throughout the course of their passage down the pollen tube, and each retains its surrounding layer of cytoplasm (fig. 8). Some male cells are vacuolate especially at the end toward the direction of movement (fig. 3, 6, 11), while others show no evidence of vacuoles at all (fig. 8). The inclusions in the gametes are similar to those in the generative cell. Mitochondria are abundant, existing as solid-staining spheres, straight and curved rods, hollow spheres, and threads. Tests for starch failed to reveal the presence of any plastids.

The male gametes were found to persist as cells in all the material examined, and there is no indication that the layer of cytoplasm around the male nuclei disappears prior to their dischargal into the embryo sac. The pollen tubes were followed until they reached the base of the style, or in those artificially germinated, for a period of about 72 hours, and mitochondria were evident in all of these. Figure 8 was drawn from a pollen tube which had penetrated the style nearly to the cavity of the ovary. The male cells are distinct, and the inclusions are well preserved. These observations agree with those of Cooper (1936), who likewise found the gametes persisting as cells after they entered the embryo sac. Although Cooper did not observe inclusions, there is no reason to suppose they disappear before the gametes enter the embryo sac, as they are present in such abundance just prior to this (fig. 6-11).

Discussion.—Different observations have been made concerning the nature of the male gametes in Lilium. As early as 1891, Guignard figured the male gametes of L. Martagon as cells. Aside from the fact that Guignard pictured astral bodies in the gametes. his figures agree in all essentials with those in the present paper. Koernicke (1906) and Strasburger (1908) properly denied the existence of centrasomes, but they also denied the existence of the male gametes as cells. Strasburger described the male nuclei as vermiform, which, he suggested, results from a type of amoeboid movement. This view was supported later by Nawaschin (1910) and Blackman and Welsford (1913). Welsford (1914) found sperm cells in the pollen tubes of L. auratum and L. Martagon, but she claimed that the cytoplasm of the sperm cells disappears before the pollen tube reaches the ovary. Somewhat similar behavior was described by O'Mara (1933) in L. regale and L. auratum, in which he reported that the cytoplasm of the sperm cells gradually dissolves, leaving the nuclei naked in the cytoplasm of the pollen tube. More recently, however, Cooper (1936), working with L. Martagon, L. auratum, and L. philippinense, saw no evidence that the male gametes lose their cytoplasm, but to the contrary observed them as cells until they reached the embryo sac. The failure of other workers to observe the cellular nature of the male gametes is probably partially due to their use of staining techniques adapted for nuclear study which do not show cytoplasm to the best advantage. Pollen tubes when destained sufficiently to show nuclear structure plainly are too faint to show the outline of the zone of cytoplasm around the gametes.

Observations on other plants with respect to the nature of the male gametes differ as widely as do those on Lilium. Recent work seems to indicate, however, that the male gametes exist as cells in many more plants than has formerly been supposed. Wulff and Maheshwari (1938), after a thorough review of the literature dealing with the male gametophytes of angiosperms, predict almost universal occurrence of sperm cells. These writers cite numerous plants formerly reported to have naked male gametes which in later investigations proved to be complete cells.

The present studies not only support the work of these investigators, but indicate further that the cytoplasm of the male gametes possesses all the inclusions which are normally present in the vegetative cells of pollen grains. The presence of vacuoles also indicates that they are organized cells. Although plastids were not observed in the cytoplasm of the male cells, mitochondria are abundant, as are transition stages in the development of plastids from mitochondria. There is no indication that these inclusions disappear during the migration of the male gametes down the pollen tube (cf. fig. 7, 3), and it is logical to suppose that the gametes retain these inclusions as long as they remain cells.

Sperm cells have been observed in the embryo sacs of several plants. Nawaschin and Finn (1913) figured the male gametes as cells in Juglans regia and J. nigra immediately after the gametes are discharged into the embryo sac. Their drawings of later stages, however, do not show the gametes as cells, but as naked nuclei with a clear space around each. Finn, in a later paper (1925), states that this clear space was intended to represent a layer of cytoplasm and maintains that the male gametes in Juglans remain as cells until fertilization. Tchernoyarow (1915), in Myosurus minimus, and Ishikawa (1918), in Oenothera, figured the male cells after they had reached the embryo sac. Both observers claimed, however, that the male cytoplasm merges with the cytoplasm of the embryo sac, leaving naked male nuclei free in the embryo sac.

Although it has not been demonstrated that the male gamete enters the egg as a complete cell, many workers disagree with the idea of a disintegration of male cytoplasm while the gamete is yet in the embryo sac. Wylie (1923) in Vallisnaria spiralis found that the male gamete remains a cell at least until it reaches the surface of the egg. Although he was unable to follow the entrance of the male gamete into the egg, Wylie thinks it highly probable that some or all of the male cytoplasm accompanies the male nucleus into the egg. Finn's (1925) observations on Asclepias Cornuti are similar to those of Wylie, and Cooper (1936) observed that the male gametes of Lilium are still complete cells when liberated into the embryo sac. In Antirrhinum majus there also is some evidence that male cytoplasm enters the egg with the male gamete (Anderson, 1936).

If the male gamete enters the egg as a complete cell, then it is obvious that male cytoplasm would be introduced during fertilization. Since it has been shown that the cytoplasm of the male gamete contains numerous mitochondria and consequently the primordia of plastids, these would be introduced into the egg. Detailed studies of the exact mode of entrance of the male gamete are needed to determine whether the entire male cell enters the egg or whether the nucleus only participates in fertilization.

#### SUMMARY

Cytoplasmic inclusions were studied in vegetative and generative cells and in the male gametes of Lilium regale Wils., L. tigrinum Ker., and L. philippinense Bak. Pollen grains were germinated both artificially and on the stigmas. Mitochondria are present both in the vegetative cell and in the generative cell of the pollen grains. When the generative cell divides, mitochondria are distributed about equally to the two male gametes. The male gametes are complete cells, consisting of a nucleus surrounded by a distinct zone of cytoplasm which is sharply delimited from the cytoplasm of the vegetative cell. The male cells contain mitochondria and transition stages in the development of plastids from mitochondria. These inclusions are derived from the cytoplasm of the generative cell. The male gametes remain distinct cells at least as long as they remain in the pollen tube, and the cytoplasmic inclusions also retain their identity. These inclusions could, therefore, be transmitted to the egg if the entire male cell participates in fertilization.

# RESPIRATION AND FERMENTATION IN THE CARROT, DAUCUS CAROTA. II. FERMENTATION AND THE PASTEUR EFFECT<sup>1</sup>

Paul B. Marsh and David R. Goddard

In the preceding paper Marsh and Goddard (1939) presented results obtained with respiratory enzyme poisons showing that in carrot roots and in young carrot leaves a large fraction of the respiration is catalyzed by an oxidase similar to or identical with the cytochrome oxidase; in mature leaves a shift occurs in the oxidase to a system insensitive to cyanide, azide or carbon monoxide. The present paper is a study of the relation between respiration and fermentation in carrot root tissue. It will be shown that inhibition of respiration by lowered oxygen pressure, by cyanide, azide, or carbon monoxide results in increased fermentation.

It has long been known that many higher plants liberate  $\mathrm{CO}_2$  when placed in pure  $\mathrm{N}_2$  or other inert gas. Alcohol is also produced in many cases (Kostychev, 1931; Stiles and Leach, 1932). The ratio alcohol/ $\mathrm{CO}_2$  produced has been investigated for many plants; considerable variation in this ratio from one plant to another has been found, the values ranging from 0 to 0.99 (Kostychev, 1931). Although there has been much speculation as to probable importance of anaerobic  $\mathrm{CO}_2$  production in higher plants, very little research has been conducted in the field since

the later years of the nineteenth century.

It is well known that in yeast (Meyerhof, 1926), animal tissues (Warburg, 1930), and in higher plants (Kostychev, 1931; Blackman, 1928) either no fermentation occurs in air or it occurs at a lower rate than under anaerobic conditions. If lactic acid production (in animal tissues) in N2 and in air, and oxygen consumption in air, be converted into terms of sugar decomposition according to the equations (1)  $C_6H_{12}O_6 \rightarrow 2CH_3CHOHCOOH$  and (2)  $C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$ , it is found in many cases that more sugar is decomposed per unit time in N2 than in air. This phenomenon of an increased rate of sugar decomposition in transferring tissues from air to N2 is known as the Pasteur effect. The literature of the Pasteur effect has been well reviewed by Dixon (1937), Turner (1937), and Burk (1937). Although the transfer of a tissue from nitrogen into air allows oxidative sugar decomposition to occur (equation 2), at the same time there is such a large decrease in the rate of sugar decomposed by glycolysis (equation 1) that the result is an overall decrease in the rate of sugar decomposition. The ratio mols lactic acid in N2- mols lactic acid in air/mols O<sub>2</sub> in respiration, is known as the Meyerhof quotient (1926). Values of this quotient lie between 1 and 2 for many animal tissues (Burk, 1937) and for yeast (Meyerhof, 1926). (In the quotient for yeast, the term "mols CO2 of fermentation" is substituted for "mols lactic acid." The expressions <sup>1</sup> Received for publication June 30, 1939.

are entirely comparable since each mol of glucose produces two mols of CO2 of fermentation just as it produces two mols of lactic acid.) If we convert the Meyerhof quotient into terms of sugar decomposition by multiplying by 3, we obtain the ratio: No. molecules glucose fermented in N2- no. fermented in air/no. glucose molecules respired. This quotient then has values between 3 and 6. Meyerhof believes that respiration has an inhibitory effect on fermentation and interprets these figures as meaning that the respiration of one molecule of glucose inhibits the fermentation of three to six molecules of glucose. However, the Meyerhof quotient is essentially merely an expression of experimentally determined facts and a criterion for the existence and magnitude of the Pasteur effect; it does not necessarily support Meyerhof's oxidative resynthesis theory or any other particular explanation of the mechanism of the phenomenon.

The only detailed explanation of the Pasteur effect which has received wide acceptance is Meyerhof's oxidative resynthesis theory. This theory states that lactic acid, the end product of anaerobic carbohydrate breakdown in muscle, undergoes in part oxidation to  $\rm CO_2$  and water and in part resynthesis to carbohydrates in air, the energy from the oxidation being utilized in the resynthesis. The experimental evidence for the theory is collected in Meyerhof (1930).

The possibility that ethyl alcohol may be in part oxidized and in part resynthesized to carbohydrate in air was suggested as early as 1879 by Wortmann (quoted by Turner, 1937). One serious objection to Wortmann's proposal is that it will not account for a lower total CO<sub>2</sub> production in air than in N<sub>2</sub> such as is observed, for example, in Meyerhof's (1926) experiments with yeast. Meyerhof (1926) has suggested that in yeast a 3-carbon intermediate undergoes oxidative resynthesis to carbohydrate. Blackman (1928) has advanced a theory that in air a 3-carbon fermentation intermediate is in part oxidized and in part resynthesized to carbohydrate, a scheme not essentially different from that proposed by Meyerhof (1926) for yeast.

The Meyerhof lactic acid resynthesis theory rests upon a rather moderate, perhaps inadequate body of experimental evidence. The validity of several assumptions involved has been called into question (Burk, 1937; Dixon, 1935). Even the fundamental assumption that the Pasteur effect is due to some effect of respiration on fermentation has been considered invalid; Lipmann (1933) has observed that the glycolysis of a muscle extract is inhibited by several auto-oxidizable dyestuffs in the presence of air, but not in N<sub>2</sub>. He considers this experiment to be a

[The Journal for November (26: 679-766) was issued November 7, 1939.]

AMERICAN JOURNAL OF BOTANY, Vol. 26, No. 10, DECEMBER, 1939.

model of the Pasteur effect, in which it is supposed that oxygen acts through some natural carrier or carriers with a fermentation enzyme, thereby inactivating it. The experimental basis of Lipmann's theory has been questioned by Michaelis and Smythe (1936).

MATERIALS AND METHODS.—Since the same general procedures and the same Fenn (1928) microrespirometer were used in this part of our study as in Part I, only those features of the methods which differed from those described in Part I (Marsh and Goddard, 1939) will be presented here.

In determining the rate of fermentation, the vessels were made anaerobic with tank nitrogen which had been freed of oxygen by passing over hot copper. A separate correction factor for the solubility of carbon dioxide was applied for each vessel. This factor was obtained from the equation:  $K_{CO_2} = V.C.$  [1 +  $\sigma$  (V<sub>1</sub>/Vg)].  $\sigma$  = absorption coefficient of  $CO_2$  in the medium;  $\sigma$  at 22° = 0.837;  $V_g$  = volume of gas space in the experimental vessel;  $V_1$  = volume of liquid in the experimental vessel; V.C. = vessel constant calculated according to Fenn (1928).

The R.Q. was determined on the same tissue, by measuring first the oxygen consumption at 10-minute intervals for one hour with CO<sub>2</sub> being absorbed by the KOH of the insets. The KOH was then removed by washing and the inset filled with an acid buffer containing a pH indicator. The movement of the bubble was again observed at 10-minute intervals for an hour. The CO<sub>2</sub> produced during the second period was calculated from the following relations:  $X_{CO_2} = X_{O_2} - X_{obs.}$ ; vol.  $CO_2 = X_{CO_2} K_{CO_2}$ ; vol.  $CO_2 = X_{O_2} K_{O_2}$ ; R.Q. = vol.  $CO_2/\text{vol.} O_2$ ;  $X_{obs.} = \text{linear movement of the bubble during second hour, where <math>X_{obs.}$  is positive if in the direction of the oxygen movement, negative if in the opposite direction;  $X_{O_2} = \text{linear movement}$  of the bubble during the first hour.

The validity of this method depends upon the constancy of the  $O_2$  and  $CO_2$  production over a considerable period (at least two hours). This was shown to be the case.

Ethyl isocyanide was prepared according to the method of Gautier (1869) and traces of HCN removed by the purification method of Toda (1926).

EXPERIMENTAL RESULTS.—Demonstration of the Pasteur effect.—Since one molecule of  $CO_2$  produced in fermentation represents three times as much glucose as one molecule of  $CO_2$  produced in respiration, if the quotient  $CO_2$  of fermentation/ $CO_2$  of respiration is greater than 1/3, the Pasteur effect is in operation. This is true only if the ratio  $C_2H_5OH/CO_2$  is close to 1 in accordance with the equation of alcoholic fermentation:  $C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2$ . Kostychev (1931) gives values of this ratio for carrot root of 100/102, 100/91, 100/86, and 100/72. However, the Pasteur effect is shown to be in operation regardless of the alcohol- $CO_2$  ratio if the fermentation  $CO_2$ /respiration  $CO_2$  ratio is more than 1.

Although a large number of figures from control vessels of other experiments made it obvious that the ratio of anaerobic to aerobic CO<sub>2</sub> was above 1/3, a separate experiment was run to determine this ratio more accurately. Two vessels were run anaerobically and three in air; the results are presented in table 1.

Table 1. The ratio anaerobic CO2/aerobic CO2.

Gas exchange in mm.3/gm./hr.							
Total CO <sub>2</sub> in air	$\mathrm{CO}_2$ in $\mathrm{N}_2$						
87 (106) <sup>a</sup>	98.1						
92.6 (113)	111						
94.3 (115)	•••						
Average 91.3	104.5						

 $^{n}$  Figures in parentheses are the oxygen consumption figures, actually experimentally determined;  $CO_{2}$  in air was calculated by multiplying these values by an R.Q. of 0.82, determined the following day.

The R.Q. was determined the following day on carrots from the same source and found to be 0.82.

The carrot root slices were tested for production of organic acids in N<sub>2</sub> by measuring the CO<sub>2</sub> output when suspended in phosphate buffer and when suspended in M/100 KHCO<sub>3</sub> in equilibrium with 98 per cent N<sub>2</sub> and 2 per cent CO<sub>2</sub>. Acids stronger than carbonic would drive CO<sub>2</sub> from the KHCO<sub>3</sub> solution and result in a higher total evolution of CO<sub>2</sub> in these vessels. Two vessels with phosphate buffer yielded an average of 63.4 mm.<sup>3</sup>/gm./hr., while two vessels in the bicarbonate medium yielded an average of 67.0 mm.<sup>3</sup>/gm./hr. This slight difference is probably entirely experimental error, and no acid is produced.

Fermentation at low oxygen pressures.—Experiments with low oxygen pressures indicated that when considerable inhibition of respiration was caused by lowering the oxygen pressure, fermentation occurred, and the R.Q.2 consequently increased. Results of these experiments are shown in table 2. The determinations with 1 and 2 per cent oxygen were not of the highest accuracy; the rates of gas exchange were not very constant with time, this apparently being due to the decrease in oxygen pressure caused by respiration. Another difficulty arises in any experiment with tissue where the oxygen tension is limiting the respiratory rate; the oxygen tension may be appreciably lower in the center of the tissue than at the outer edges, and the rate of fermentation may not therefore be uniform in all cells. These criticisms are probably not too serious, since we obtained results at low oxygen tensions which are in good agreement with those obtained in cyanide or azide, reported later in this paper, which are free from either of the two objections suggested here.

 $^2$  Since in fermentation CO<sub>2</sub> is produced without a corresponding oxygen consumption, the respiratory quotient or ratio of total CO<sub>2</sub> produced to O<sub>2</sub> consumed is higher when both processes are occurring simultaneously than in the case of respiration alone.

1	(93.2)	19.2	66.5	3.3	79

<sup>&</sup>lt;sup>a</sup> The parentheses indicate the use of a single control vessel to calculate percentage inhibition of respiration of more than one sample.

The determinations were sufficiently accurate to indicate the general trend of fermentation, increasing as lower oxygen pressures were used and as respiratory inhibition increased. These results might, however, be interpreted according to Lipmann as an effect of oxygen acting upon a fermentation enzyme by some other pathway than through the respiratory chain. In view of the current debate upon this question it seemed desirable to try to determine which explanation is correct, Lipmann's or the earlier idea that respiration itself has a direct inhibitory effect on fermentation.

Aerobic fermentation induced by cyanide, azide, carbon monoxide.—At this point a convenient method of separating the respiration and fermentation mechanisms in the carrot root was found. It was dis-

covered that carrot root fermentation was unaffected by the respiratory poisons (Marsh and Goddard, 1939) cyanide and carbon monoxide, as is the case with yeast (Warburg, 1925, 1927), and was only slightly sensitive to low concentrations of the respiratory poison sodium azide. Table 3 presents figures on these results.

20.5	60.3	42.9	2.99	62.3	78.2	25.2	1.25	

 $<sup>^{</sup>a}$  Fermentation CO<sub>2</sub> was calculated by multiplying O<sub>2</sub> consumption by 0.85, the average R.Q. of unpoisoned tissue (table 6), and subtracting the resulting figure from total CO<sub>2</sub>.

It was then discovered that cyanide, azide, and carbon monoxide all induced aerobic fermentation in the carrot root (table 4, 5, 6), and for cyanide and carbon monoxide it was shown that this effect is reversible (table 5). If Lipmann's explanation of the action of an oxidizing mechanism, other than respiration, on a fermentation enzyme is correct,

<sup>&</sup>lt;sup>b</sup> Similar tissues but not same sample.

<sup>&</sup>lt;sup>b</sup> In this experiment we obtained R.Q. in 95% N<sub>2</sub>, 5%  $O_2 = 50.3$  mm. $^3$ CO<sub>2</sub>/gm./hr.  $\div$  63.3 mm. $^3$ O<sub>2</sub>/gm./hr. = 0.79.

then we must assume that each of these poisons, in the concentrations used, inhibits the action of Lipmann's oxidizing chain as well as respiration. A further difficulty is that the inhibition of the oxidation of the fermentation system would have to be light reversible. Lipmann's theory is consistent with our results only if the inhibition of fermentation by oxygen is catalyzed by cytochrome oxidase. Ball (1939) has suggested that the ratio of oxidized cozymase/ reduced cozymase may be considerably different in aerobic and anaerobic cells. Cozymase + specific protein constitutes the enzyme reducing acetaldehyde to alcohol. Further, cozymase + other specific proteins constitute the dehydrogenases catalyzing the oxidation of pyruvic acid and triosephosphates, etc. Since cozymase is not autoxidizable, the ratio of oxidized/reduced cozymase will not be determined by oxygen pressure alone. It is probable that cozymase undergoes oxidation by means of the coenzyne factor (diaphorase) + unknown carriers, cytochrome, cytochrome oxidase. Our results are consistent with Ball's suggestion, but in no way substantiate it.

One cannot calculate a Meyerhof quotient for tissues which do not glycolyse or ferment in air, for in these cases it is possible that not all of the respiration is necessary to completely prevent aerobic fermentation. However, it is possible to calculate a term essentially equivalent to a Meyerhof quotient, by using the respiratory and fermentation rates at two different levels of cyanide poisoning at both of which aerobic fermentation occurs. Similar calculations may be made from the data at two oxygen pressures, both sufficiently low to give fermentation but at different rates. Let X represent a concentration of

cyanide at which fermentation occurs, and Y a higher concentration of cyanide, then:  $CO_2$  of ferm. in  $Y-CO_2$  of ferm. in  $X/O_2$  of resp. in  $X-O_2$  of resp. in Y= "M.Q."

Due to experimental variation, our values with cyanide are not accurate enough to make calculations over narrow ranges of cyanide concentrations. If, however, we let  $X = 1.0 \times 10^{-4}$  M cyanide and  $Y = 8 \times 10^{-4}$  M cyanide, then we obtain (using average figures from table 6) for the above quotient a value of 29.8-1.2/46.2-14.3 = 0.90.

If we calculate a similar ratio (likewise expressing the efficiency of respiration in inhibiting fermentation) by using the average fermentation and respiration values for  $10^{-4}$  M cyanide (table 6) and the fermentation value in 100 per cent  $N_2$  (table 1), we obtain a quotient of 104.5-1.2/46.2=2.24. If we make the calculation between  $8\times 10^{-4}$  cyanide and 100 per cent  $N_2$ , the ratio equals 104.5-29.8/14.3=5.22, indicating that the first few per cent of respiration are more efficient in inhibiting fermentation than are additional increments.

The general trend of the effect of respiration on fermentation may be seen clearly from figure 1; as respiration is inhibited beyond about 50 per cent, R.Q. rises from about 0.85 to about 3. It is, of course, highly probable that in nature the cells of the carrot root, particularly those near its center where oxygen diffusion would be a rate-limiting factor, do not respire nearly so fast as do the thin slices used in our experiments.

Inhibition of the Pasteur effect.—Warburg (1926) has shown that M/1000 ethyl isocyanide inhibited neither respiration nor fermentation of Jensen sarcoma but allowed fermentation (glycolysis)

to proceed at the normal anaerobic rate in air, unhindered by respiration. Upon transfer of the tissue to a poison-free medium, the aerobic fermentation returned practically to its normal respiration—limited value. Reference to table 7 shows that carrots

do not react in this way to ethyl isocyanide. If the Pasteur effect were poisoned by the isocyanide, the expected  $CO_2$  production in the presence of the poison would be the sum of the aerobic  $CO_2$  and the anaerobic  $CO_2$ . Since the anaerobic  $CO_2$  is 1.15 times the aerobic  $CO_2$ , the expected value in the poi-

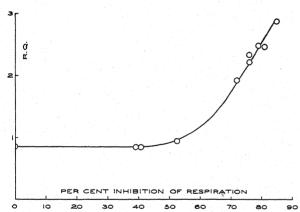

Fig. 1. The relation between R.Q. and respiratory inhibition by cyanide.

soned tissue is 2.15 the  $CO_2$  of the unpoisoned control, or  $2.15 \times 158 = 340$ . The experimentally determined value is 153.

Genevois (1927) has shown that in *Lathyrus* low concentrations of cyanide which do not inhibit respiration do induce aerobic fermentation, thus poi-

soning the Pasteur effect. Laser (1937a) has shown that in several animal tissues low oxygen pressures which do not lower the respiratory rate induce aerobic glycolysis. Further, Laser (1937b) has shown that in such tissues 80 per cent CO does not inhibit oxygen consumption but does poison the Pasteur effect, allowing aerobic glycolysis to occur. Inspection of table 6 shows that in cyanide concentrations from  $10^{-6}$  to  $1.0 \times 10^{-4}$  no aerobic fermentation occurs. Genevois' results with Lathyrus were not shown in carrots. The results listed in table 2 show that in 5 per cent oxygen with a respiratory inhibition of 27.5 per cent no fermentation occurs. Thus Laser's results with animal tissue could not be duplicated here. We have insufficient data on CO at various pressures to settle the problem of whether the Pasteur effect can be poisoned by CO in carrots. The fact that our results do not agree with those of Warburg, Laser, and Genevois, is not meant to question their results, but to point out differences in the Pasteur effect in different organisms.

#### SUMMARY

The results presented in this paper clearly demonstrate the existence of the Pasteur effect in carrot root tissue. Further, they show that with cyanide inhibition of respiration in excess of 45-50 per cent there is a direct effect of respiration on the inhibition of fermentation. Sodium azide and carbon monoxide also induce aerobic fermentation, and the carbon monoxide effect is reversed by light. These results are not consistent with the Lipmann theory of the oxidation of a fermentation enzyme unless the oxidation is catalyzed by cytochrome oxidase. However, they are consistent with, but give no proof for, the Meyerhof oxidative resynthesis theory. Direct proof of this theory for a higher plant may be obtained only by simultaneous analysis for carbohydrate, alcohol, CO2, and O2. Such information is not available for any single plant. The Pasteur effect is not poisoned by ethyl isocyanide, low oxygen pressures, nor by cyanide.

## GROWTH SUBSTANCES IN AGAR 1

## William J. Robbins

ONE of the commonest substances employed to prepare a solid medium for the cultivation of microorganisms is agar-agar. It is made from marine algae, chiefly *Gelidium corneum* (Smith, 1905) and was first used by Frau Fannie Hesse in 1881 (Hitchens and Leikind, 1939); the first published notice of its use was by Koch (1882).

Added at concentrations of 0.5 per cent or more to solutions containing suitable foods and nutrients, it furnishes a solid or semi-solid substratum upon which yeasts, bacteria, and filamentous fungi may be grown. It is usually regarded as an inert agent, though some organisms have been reported which digest it (Goresline, 1933). Since it is considered primarily as a convenient means of solidifying a liquid medium, the amount employed depends chiefly upon the degree of solidity desired and upon convenience in filtration. Commonly added in amounts sufficient to make a 1.0 or 2.0 per cent solution, some prefer lower concentrations, and others have found superior results from media containing as much as 3.0 or 4.0 per cent.

Since agar is prepared from the algae by extraction with hot water, it contains a variety of inorganic salts and organic materials. Smith (1905) gives the following percentage analysis for a sample of kanten or crude agar: water, 22.29; protein, 6.85; fiber, 6.73; carbohydrates, 60.32 and ash 3.81. The agar used in preparing culture media is purified to various degrees, some of the ash and other materials being removed in the process, and preparations of different degrees of purity are available on the market. According to a letter from the Digestive Ferments Company, Difco agar contains on the average 0.29 per cent nitrogen and 3.0 per cent ash. According to Gortner (1929), agar is a sulfuric acid ester where the ester group is a complex polysaccharide and the gelatinization is that of a salt of an agar sulfuric acid.

<sup>1</sup> Received for publication July 31, 1939.

Assistance in this work was furnished by the personnel of Works Progress Administration Official Project No. 465-97-3-70. The assistance of Frederick Kavanagh and V. N. Sergievsky also is acknowledged.

Observations that the growth of organisms on an agar medium is superior to that in a liquid medium have been reported from time to time. Robbins and White (1936) found agar or a water extract of agar to exert a favorable influence on the growth of excised corn roots. Lignières (1919) found 0.25 per cent agar favorable for the cultivation of anaerobes. Hitchens (1921) reported a beneficial effect of dilute agar (down to 0.05 per cent) upon the growth of aerobic and anaerobic bacteria. Lignières and Hitchens accounted for the beneficial action of the agar by its effect upon the oxygen tension in the medium. Itano and Tuiji (1934) found that agar of lower grade supported the better growth of Azotobacter, B. subtilis, and Saccharomyces cereviseae. They believed that this was caused by a larger quantity of some stimulating substance—for example, iodine-in the cruder agar. Umbreit (1939) observed growth of species of Proactinomyces to be better on agar media than on corresponding liquid media. He believed the benefit to be a surface effect acting indirectly through perhaps the oxidation-reduction potential. The action of agar might be ascribed to various causes including the inorganic substances it contains, especially the trace elements, its adsorptive power because of its colloidal character, a favorable effect upon the hydrogen-ion concentration, a physical effect upon growth, its effect upon the oxygen supply, its nitrogen content, its action in lowering the surface tension or the presence of growth substances. The present paper presents evidence that agar exerts a favorable effect upon Phycomyces Blakesleeanus and that this effect is probably because of the presence in commercial agar of growth substances.

MATERIALS AND METHODS.—The strain of *Phycomyces Blakesleeanus* used was originally secured from Dr. A. F. Blakeslee. Petri dishes 10 cm. in diameter and 1.5 cm. deep were used as culture vessels. Sterile conditions were maintained throughout; the liquid or agar media were sterilized in an autoclave at 15 lbs. pressure for 20 minutes. The *Phyco-*

Table 1. Spore germination of Phycomyces on Difco agar and on the same agar purified by extraction with aqueous pyridine. Counted after 20 hours. All media contained same amounts of dextrose, asparagine, mineral salts, and thiamin.

Medium	No. spores counted	No. spores germ.	Percentage germ.	Approximate length of hyphae, mm.
1.0% Agar	1,103	45	4.0	0.60
1.0% Purified agar	1,165	14	1.2	0.12
0.5% Agar		20	1.8	0.35
0.5% Purified agar		7	0.5	0.12

myces cultures were incubated at 25°C. in weak diffuse light. Distilled water was used in preparing the media, and the chemicals were of chemically pure grade. The thiamin was Merck's synthetic.

Two basic culture solutions were used, each of which was supplemented with 0.01 ppm. boron, 0.02 ppm. molybdenum, 0.20 ppm. iron, 0.15 ppm. zinc, 0.04 ppm. copper and 0.02 ppm. manganese. Solution 1 contained per liter 50 g. dextrose, 0.5 g. asparagine, 0.5 MgSO<sub>4</sub> · 7 H<sub>2</sub>O, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, and 0.25 mg. thiamin. Solution 2 contained per liter 100 g. dextrose, 1.0 g. asparagine, 0.5 g. MgSO<sub>4</sub> · 7 H<sub>2</sub>O, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, and 0.25 mg. thiamin.

EXPERIMENTAL.—Agar beneficially affects the development of *Phycomyces*. From macroscopic examination it appeared that evident mycelium developed in a liquid medium of mineral salts, asparagine, dextrose, and thiamin one or two days later than on the same medium to which 1.0 or 2.0 per cent agar was added. The difference in growth seemed less pronounced as the cultures became older. It might reasonably be suggested that the greater early development on the agar medium was caused by the better oxygen supply available to the organism on the surface of the solid medium as compared to that in a

liquid medium where the spores and early mycelial growth were submersed.

However, such an explanation is inadequate because the beneficial effect of the agar increased with its concentration and the organism grew in these instances on the surface with similar access to oxygen. Spore germination, growth, especially early growth, and the formation of gametes and zygotes were all beneficially affected by increasing the concentration of agar.

For example, to solution 1 sufficient Difco agar was added to make a 0.5 per cent and a 1.0 per cent solution. Approximately 25 ml. of these media were poured into Petri dishes, and by means of a platinum loop drops of a spore suspension of *Phycomyces* in sterile distilled water were placed on the surface of the solidified agar. Spore counts made after 18 hours' incubation at 25°C. showed 4.0 per cent germination on the 1.0 per cent agar and 1.8 per cent on the 0.5 per cent agar. The hyphae arising from the spores on the 1.0 per cent agar were on the average about twice as long as those on the 0.5 per cent agar (table 1).

The effect of agar concentration on growth may be illustrated by the following experiment. In this

instance solution 1 containing 0.05 per cent asparagine and the same solution containing 0.4 per cent asparagine were used. With each of these solutions media containing 0.5 per cent, 1.0 per cent, 2.0 per cent, 3.0 per cent, and 4.0 per cent agar were prepared, poured in Petri dishes, and inoculated in the center of each dish with a drop of a spore suspension of the plus strain of *Phycomyces*. Triplicate plates were used for each agar concentration and each asparagine concentration. In addition to general observations colony diameters were measured at intervals, and after 110 hours the agar was melted,

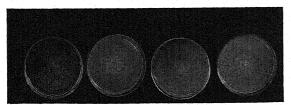

Fig. 1. Effect of concentration of agar on growth of *Phycomyces*. From left to right 1.0 per cent agar, 2.0 per cent, 3.0 per cent, 4.0 per cent. All contained per liter 50 g. dextrose, 0.5 g. asparagine, 0.5 g. MgSO<sub>4</sub> · 7 H<sub>2</sub>O<sub>7</sub>, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, 0.25 mg. thiamin and mineral supplements. Age 63 hours.

mycelium washed in hot water, and dry weights were determined by drying at 100°C. (table 2).

Growth on the 0.5 per cent agar after 44 hours was rather sparse; it increased as the concentration of agar increased, the heaviest growth appearing on the highest concentration of agar. The difference was more marked between that on the 1.0 per cent and on the 2.0 per cent agar than between that on other successive steps in the concentrations used (fig. 1). The growth on the media containing the larger amount of asparagine was somewhat less extensive though perhaps heavier. Colony diameters (table 2) increased with the concentration of agar, though the differences in growth were greater than indicated by the colony diameters, especially between the growth at 0.5 per cent and 1.0 per cent agar and that at higher concentrations, because colony diameters do not measure density. The measurements of colony diameters at the end of 62 and 110 hours showed similar effects of increasing concentration of agar. As the colonies aged, the heaviness of the mat increased on the more dilute agars so that the appearance was more nearly alike on all concentrations than in the first day or two of development. The dry weights at the end of 110 hours (table 2) showed the effect of the agar concentration more markedly with the larger amount of asparagine.

The production of gametes and zygotes by *Phycomyces* is influenced by a number of factors, including the concentration of agar. On solution 1 containing 1.0 per cent agar gametes were rarely produced if the plates were inoculated with a drop of a spore suspension of the plus strain at one edge and the minus strain at the other so that the distance between the two drops was about 8.5 cm. If the agar

concentration was increased to 2.0 per cent, a yellowish line of gametes formed, and a few zygotes with appendages developed. With 3.0 per cent agar the thickness of the line of gametes and the number of zygotes with appendages was still greater. For example in 4 Petri dishes of solution 1 with 1.0 per cent agar inoculated with plus and minus strains as described above no gametes were produced. With the same solution containing 3.0 per cent agar a yellowish line of gametes was formed, and an average per plate of 62 zygotes with appendages was counted (fig. 2).

Of the various explanations which might be offered for the beneficial effects of agar described above, oxygen supply for the reasons discussed earlier does not appear a probable one. Although Difco agar contains some nitrogen growth of Phycomyces on a Difco agar medium without added nitrogen but containing sugar, mineral salts, and thiamin was extremely scant indicating that the nitrogenous compounds in the agar are not in an available form or in sufficient amount to be significant. Furthermore, the beneficial action of increased concentration of agar was evident when the asparagine was raised to 0.4 per cent. It appears unlikely that mineral elements are concerned, since a group of micro-elements was added to the solution cultures and to the various concentrations of agar. Changes in hydrogen-ion concentration also do not appear significant, since the KH<sub>2</sub>PO<sub>4</sub> added would be expected to give much the same reaction to the media in all the plates. The agar might adsorb some ions and better balance the

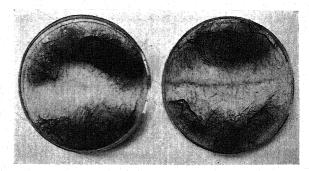

Fig. 2. Effect of concentration of agar on formation of gametes and zygotes by *Phycomyces*. Left. 1.0 per cent agar; right, 3.0 per cent agar. Both inoculated at opposite edges with drop of spore suspension. Both contained per liter 100 g. dextrose, 1.0 g. asparagine, 0.5 g. MgSO<sub>4</sub>· 7 H<sub>2</sub>O, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, 0.25 mg. thiamin and mineral supplements. Age 11 days.

solution or it might affect development through its physical characters which would change somewhat with concentration. It appears, however, that these possibilities also may be eliminated, because it was found that beneficial materials could be removed in part by extraction with methyl alcohol or with aqueous pyridine.

In an attempt to extract the beneficial material, 5 g. of Difco agar were dissolved by heating in 100 ml. of distilled water. The hot liquid was poured

with stirring into 200 ml. of redistilled methyl alcohol. The precipitate was centrifuged off, redissolved in hot water and reprecipitated with alcohol. The precipitate was again removed by centrifuging, washed with three 30 ml. portions of 60 per cent methyl alcohol, and dried. The methyl alcohol extracts were combined and evaporated by boiling to small volume. About one-half of the original 5 g. of agar was recovered in the precipitate, the balance remaining in the methyl alcohol extract. Media were prepared consisting of solution 2 containing 1.0 per cent Difco agar, 1.0 per cent agar purified by extraction with methyl alcohol, or the methyl alcohol extract sufficient to make 1.0 per cent agar and poured into Petri dishes. Triplicate plates of each medium were inoculated with three drops of a spore suspension of the plus strain of Phycomyces arranged in a line across the plate and three drops of a spore suspension of the minus strain arranged in a parallel line 2.5 or 3 cm. from the first. The mycelial growth was most rapid on the plates containing 1.0 per cent Difco agar and considerably less rapid on those plates containing the purified agar. The growth on

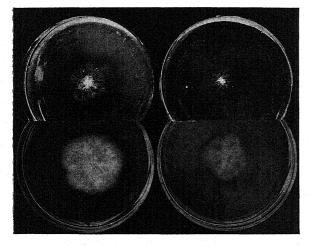

Fig. 3. Effect of purification of agar on growth of *Phycomyces*. Left, 0.5 per cent Difco agar; right, 0.5 per cent Difco agar purified with pyridine. Above at end of 48 hours; below, 63 hours. All contained per liter 50 g. dextrose, 0.5 g. asparagine, 0.5 g. MgSO<sub>4</sub> · 7 H<sub>2</sub>O, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, 0.25 mg. thiamin and mineral supplements.

the methyl alcohol extract was better than that on the purified agar and not as good as that on the unpurified. Under the conditions of inoculation described a medium heavy line of yellowish gametes developed on the unpurified agar plates; on the purified agar the line was thin (fig. 6); on the agar extract it was intermediate between the two given above.

It appeared from this experiment that materials beneficial to the development of *Phycomyces* were present in Difco agar and that they could be extracted in part with dilute methyl alcohol. However, the extraction was only partially successful and considerable agar was lost in the process. An attempt

was therefore made to extract the agar with 5.0 per cent aqueous pyridine.

Fifty grams of powdered Bacto agar were extracted at room temperature over a period of 48 hours with 500, 300, and 500 ml. of 5.0 per cent aqueous pyridine. The extracts were combined, the pyridine distilled off, and the solution evaporated to 100 ml. The extract contained 2.5 per cent solid material. The agar was washed twice with 95 per cent ethyl alcohol and air dried. More than 45 g. of the original 50 g. were recovered.

Solution 1 and the same solution with 0.4 per cent asparagine were prepared with 0.5 per cent, 1.0 per cent, 2.0 per cent, 3.0 per cent and 4.0 per cent of the purified agar poured into Petri dishes and inoculated in the center of each plate with a drop of a spore suspension of the plus *Phycomyces*. Triplicate plates were used with each agar concentration.

Colony diameters were measured and dry weights determined. The growth on the purified agar was distinctly poorer than on the unpurified agar (table 2, fig. 3). For example, at the end of 44 hours the colony diameter on 0.5 per cent Difco agar was 2.5 mm.; on the purified agar 1.2 mm.; at the end of 110 hours the dry weight on the 0.5 per cent Difco agar was 41.0 mg., on the purified agar 16.7 mg. The differences between the growth on the purified and unpurified agar were evident on the media containing 0.05 per cent asparagine and on those containing 0.4 per cent asparagine. Increasing the concentration of the purified agar had less effect than increasing the concentration of the unpurified agar.

It appeared from these experiments that agar extracted with aqueous pyridine was less favorable for the growth of *Phycomyces* than unextracted agar. That this was because of the removal by the extraction of some beneficial factor or factors and not an effect caused by a residuum of pyridine or the development of injurious products by the treatment was demonstrated by the effect of the addition of the extract to the purified agar. In this instance *Phycomyces* was grown in Petri dishes as before on solution 1, plus 1.0 per cent purified agar, and on the same medium plus the pyridine extract equivalent to 1.0 per cent, 2.0 per cent and 4.0 per cent agar. The growth on the media to which the extract was

Table 3. Colony diameters and dry weights of Phycomyces Blakesleeanus grown on Difco agar purified by extraction with aqueous pyridine and same agar plus different amounts of extract. All cultures contained same amount of dextrose, asparagine, mineral salts, and thiamin.

Age 63 hours.

purified Difco agar (fig. 5). From these experiments it was concluded that agar contains some substance or substances which favor spore germination, growth, and the production of gametes and zygotes by *Phycomyces*. These substances can be extracted from the agar by aqueous pyridine.

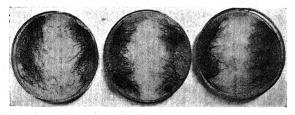

Fig. 5. Purification of agar and gametic reproduction by *Phycomyces*. Left, 1.0 per cent Difco agar; center, 1.0 per cent Difco agar purified by extraction with aqueous pyridine; right, purified agar plus extract equivalent to 1.0 per cent agar. All contained per liter 50 g. dextrose, 0.5 g. asparagine, 0.5 g. MgSO<sub>4</sub> · 7 H<sub>2</sub>O, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, 0.25 mg. thiamin and mineral supplements. Plates inoculated in 6 places in two lines 2.5 cm. apart.

Substances having similar effects are present in brown sugar, potato, corn meal, and oatmeal. A detailed report of the effects of these substances on *Phycomyces* will not be made here. Their effects are marked. For example, in one experiment the percentage of germination of *Phycomyces* on solution 1 containing 1.0 per cent Difco agar was 3.6 per cent

at the end of 22 hours and 5.5 per cent at the end of 46 hours. On the same medium to which was added a concentrated extract of white potato equivalent to 2.75 g. of potato per plate the germination was 22.0 per cent and 30.5 per cent at the time intervals indicated. Furthermore, the addition of potato extract to the agar purified with methyl alcohol or aqueous pyridine increased the production of gametes and zygotes (fig. 6).

What are the beneficial substances in the agar? It appears probable that they are growth substances rather than minerals or sources of nitrogen, since both the latter seem to be eliminated for the reasons given above. That agar contains thiamin or its intermediates and biotin was demonstrated by the growth of *Phycomyces* and of *Ashbya* (Robbins and Schmidt, 1939). Development of the *Ashbya* in a

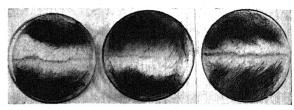

Fig. 6. Effect of purification of agar and potato extract on gametic reproduction by *Phycomyces*. Left, 1.0 per cent Difco agar; center, 1.0 per cent Difco agar purified by methyl alcohol; right, 1.0 per cent purified agar plus potato extract equivalent to 2.75 g. potato per plate. All contained per liter 50 g. dextrose, 0.5 g. asparagine, 0.5 g. MgSO<sub>4</sub> · 7 H<sub>2</sub>O<sub>4</sub>, 1.5 g. KH<sub>2</sub>PO<sub>4</sub>, 0.25 mg. thiamin and mineral supplements. Inoculated in 6 places in two lines 2.5 cm. apart.

medium supplemented with an agar extract made with aqueous pyridine indicated the presence of 0.041 gamma of biotin per g. of agar, and the growth of *Phycomyces* in a medium lacking thiamin but supplemented with the agar extract indicated the presence of traces of thiamin or its intermediates.

If a growth substance is concerned in the favorable effects of agar described above, it is not thiamin or its intermediates, since an excess of this growth substance was added to the media. It is not vitamin B<sub>6</sub>, because the addition of a pure synthetic preparation of this compound to a medium containing thiamin had no marked beneficial effect upon either growth or the gamete formation of Phycomyces, which is contrary to the report by Sinclair (1938) that vitamin  $B_6$  has a favorable effect in the presence of thiamin. It would not seem to be biotin, since Kögl and Fries (1937) found biotin ineffective on the growth of Phycomyces in the presence of thiamin. Other growth substances which might be suspected could not be tested, because they were not available in pure form.

Discussion.—While in our opinion these experiments demonstrate the presence in agar of growth substances beneficial to the development of *Phycomyces*, final and conclusive proof of this must wait the identification of the substances concerned and the demonstration of their effects in pure form. This

must be borne in mind in the following discussion which is based on the assumption that we are dealing

with growth substances.

On that basis it follows that Phycomyces requires for maximum development a growth substance other than thiamin. This unknown exists in agar, potatoes, corn meal, oatmeal, brown sugar, and doubtless many other materials of natural origin. While Phycomuces is unable to synthesize thiamin and must be supplied with that growth substance or its intermediates if it is to grow at all, we believe it makes some of the unknown material, though insufficient for maximum development. The situation is somewhat analogous to that which exists for the strain of excised tomato roots with which we have worked (Robbins and Schmidt, 1939a, 1939b). The tomato root also makes no thiamin and will not grow without an external supply of thiamin (or thiazole). In the presence of thiamin, growth of the tomato root is limited by its ability to synthesize vitamin B6, and until the amount of this substance made by the root is supplemented by an outside supply growth is slow, even in the presence of thiamin. With Phycomyces the second growth substance is not vitamin B<sub>6</sub> but another as yet unknown. It is entirely possible, of course, that deficiencies of more than one unknown growth substance are involved in the development of this fungus.

Even though the experiments described here have been concerned primarily with *Phycomyces*, it is probable that other organisms also will be found to respond favorably to the growth substances in agar. The beneficial effects of an agar extract on *Ashbya* and on excised corn roots have already been cited. At the same time organisms will doubtless be found which will not evidence any benefits. This would be in accordance with the concept we have formed of the relation of growth substances to organisms. Many are essential for the development of any organism. Some organisms form all in amounts adequate for growth; others lack the ability to make one or more than one in sufficient amounts, and the de-

ficiencies vary with the organism.

It is of some interest to note that for *Phycomyces* a critical point seemed to be between 1.0 per cent and 2.0 per cent Difco agar. A concentration of 1.0 per cent and below was much less effective than 2.0

per cent and above. This would suggest that for the media used the amount of growth substance in the former concentration is inadequate and in the latter nearly adequate. This critical concentration would of course vary with the purity of the agar. Dr. B. O. Dodge has advised us that he has long had the impression that Difco corn meal agar made with 2.0 per cent agar is more favorable for the perthicial development *Neurospora* than the same medium made with 1.0 per cent agar.

In any event it seems clear that agar as a medium for investigations of the growth of organisms and particularly for investigations on growth substances cannot be regarded as an inert material; it is necessary to take into consideration the possibility that it may influence results because of the growth substances it contains. At the same time it appears also that thiamin is not the only growth substance which *Phycomyces* requires from without, and experiments in which this organism is employed must take that

fact into consideration.

#### SUMMARY

A beneficial effect of Difco agar upon the spore germination, the growth and the formation of gametes and zygotes by Phycomyces Blakesleeanus was observed. The beneficial material could be extracted in part from the agar with dilute methyl alcohol and more completely with aqueous pyridine. Since the media used contained minerals (including micro-essential elements), sugar, asparagine, and thiamin, it is believed the beneficial action of the agar was caused by unknown growth substances. Agar was found to contain appreciable quantities of biotin and traces of thiamin or its intermediates. Potato, brown sugar, oatmeal, and corn meal favorably affected the development of Phycomyces in the presence of thiamin and probably contain the same unknown growth substances believed to be in agar. The possibility of the occurrence of growth substances in agar is a factor which must be considered in using that material in experiments with living organisms.

# STIMULATION OF GROWTH IN ASPERGILLUS NIGER UNDER EXPOSURE TO LOW VELOCITY CATHODE RAYS 1

C. E. Buchwald and R. M. Whelden

STIMULATION OF the growth of unicellular organisms under exposure to low dosages of various ionizing radiations has been rather frequently reported in the literature.2 In particular, stimulation of growth of yeasts and molds in wide variety has been reported when these organisms have been exposed to very low dosages of X-rays, radium emanations, and ultraviolet radiation. This effect, on the other hand, has been denied by many workers—a fact which seems to warrant the publication of this paper.

For several years we have been engaged in a study of the various effects which may be obtained when spores of the Ascomycete fungus Aspergillus niger are exposed in high vacuum low voltage cathode ray beams. This work has been partly reported elsewhere (Buchwald and Haskins, 1938; Whelden, 1938; Haskins, 1938; Cooper, et al., 1939).

Early in the course of this work it was observed that after irradiation at certain voltages and currents there was a marked acceleration in the rate and in the extent of swelling of the spores. Because of the uniqueness of the ionizing radiation, the high degree of uniformity of the biological material, the very large amount of data taken, and the number and character of statistical tests which have been applied, we feel that we have been able to demonstrate conclusively the occurrence of stimulation.

Source and character of radiation and radia-TION PROCEDURE.—The low voltage cathode ray tube which was used in this work has been rather fully described elsewhere (Buchwald and Haskins, 1938; Haskins, 1938; Cooper, et al., 1939). It consists essentially of an electron gun for the acceleration of electrons from a hot filament and a chamber in which the spores are placed for the irradiation process. Auxiliary apparatus evacuates the gun and chamber, supplies the high voltage for accelerating the electrons, and measures the number of electrons striking the organisms. The combined assembly, as it appears during a run, is shown in figure 1.

Within the raying box is a rotatable sample holder (fig. 2) upon the periphery of which can be clipped twenty-three small brass slides, chromium plated and highly polished. Spores from a culture of the fungus at least six weeks old are carefully spread

<sup>1</sup> Received for publication August 3, 1939.

<sup>2</sup> Chavarria and Clark, 1924; Hutchinson and Newton, 1930; Luyet, 1932; Nadson, 1925; Nadson and Philippov, 1928; Smith, 1935; Zeller, 1926.

upon these slides with a camel's hair brush, so that each spore is separated from its neighbors, on the average, by a distance five to ten times its own diameter. The slides are clipped into position on the rotating cylinder, the raying chamber is sealed and evacuated to a pressure of the order of 10<sup>-5</sup> mm. of mercury, and the spores are scanned by the beam from the electron gun as they travel across the slit system connecting gun and raying box. A Faraday cage, mounted within the cylinder, permits an accurate measure of the total number of electrons which strike each slide, and this number can be varied within wide limits. When all the slides have been treated, air is admitted to the raying box and the electron gun, the slides containing the spores are removed, and the spores are "printed" onto plates of potato-maltose agar by gently pressing the slide face to the agar surface and removing it immediately. Great care was constantly taken to prevent any disturbance of the spores while on the surface of the slides, particularly when air was admitted to the apparatus. Care was also taken that all spores used should be of nearly uniform age.

CULTURING AND COUNTING PROCEDURE.—Cultures were started from all samples of a given run simultaneously. The agar plates were incubated for from 6 to 7.5 hours, out of direct sunlight, at 25°C.-28°C. Only a small central portion of the slide was scanned by the electron beam. The irradiated strip took the form of a band with sharp edges, extending at right angles to the long axis of the slide. The spores on the end of each slide therefore constituted a control for that slide. In addition, an entire control slide was run for each twenty-three rayed ones. It was mounted inside the drum where it was entirely shielded from the electron beam.

When the spores had been transferred to the agar surface of the culture plates, small groups were marked in each set so that they could be readily distinguished at any time. These marked groups usually included about thirty spores so distributed that their growing germ tubes would not become entangled too quickly. Camera lucida drawings were then made of all the spores of these groups of spores at definite intervals of time until growth of the tangled hyphae made it impossible longer to follow the development of each spore. For any single group of spores this was usually not more than twelve to fourteen hours. In a few cases a selected group of spores became "lost" or unrecognizable during the period of observation. In such cases a group from the immediate vicinity was chosen as a substitute.

From the series of drawings so made, measurements were taken directly of the dimensions of each spore. Measurements were made to the nearest halfmicron. The series of measurements for each set of spores was tabulated separately and afforded a good comparison of the relative rates of change of the spore dimensions for the various sets throughout the observation period. Spores which were "inactive" (i.e., in which neither germination nor swelling occurred during the experiment) were not counted. The value taken for the diameter of each spore, and so listed, was in fact the average of two diameters, taken at right angles.

RESULTS.—Data of diameters from a typical group of spores are shown in table 1. Occasional figures in the table are missing, an omission caused by the fact that at the moment of that observation the spore was overlooked due to its position on the agar plate. From such tabulations as these, averages and probable errors were computed in the usual fashion, representing the average rate of change of cell diameter with time for each group of spores studied. including controls.

In figures 3 and 4 are shown plots of the average rate of change with time of two irradiated runs. compared with their control groups. Additional aver-

ages are shown below.

Discussion.—From a statistical study of the data and an examination of the curves, it becomes evident that (a) the swelling of the irradiated spores starts earlier in the culturing time of the spore for irradiated than control samples; (b) the average rate of swelling is higher for irradiated spores; (c) the size of the irradiated spores at any given time averages larger; (d) a larger percentage of irradiated spores have germ tubes.

It is evident that, if such far-reaching conclusions are to be drawn, copious data must be available, and must be very carefully analyzed (statistically). For this reason, a very large amount of data was taken. and no fewer than three tests were applied to it to determine its statistical significance: the binomial law (Fry, 1938); "Student's" t-test (Fisher, 1936), and Pearson's "Chi-squared" test (Frv. 1938; Fisher, 1936).

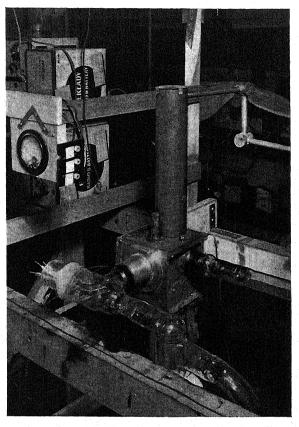

Fig. 1. General view of apparatus.

The binomial law is designed to give the probability that the observed grouping of the data can be accounted for entirely by chance. This test must be applied with discretion. If n represents the total number of times that the irradiated spores were measured and m is the number of measured values which are less than the control, then  $P_s = n!/$

 $(n-m)!m!(\frac{1}{2})^n$ , where  $P_s$  represents the probability that the observed distribution of values of the data is a matter of pure chance alone. This test is useful in limited cases only.

"Student's" t-test is capable of yielding information concerning the significance of the observed statistical difference between the control and the irradiated material. It can tell the value of the probability that, had both groups of spores been treated similarly, the differences between them, arising purely from chance causes, would have been as great as

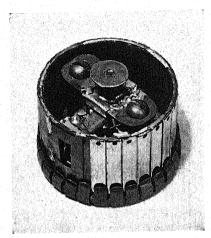

Fig. 2. Rotatable slide holder.

those observed. The smaller the value of this probability, of course, the more certain is it that the irradiated and the control spore populations differed because of their experimental treatment.

Pearson's "Chi-squared" test gives the same information as the t-test, but instead of being applied directly to the measurements of single spores or the average measurements of several of them, it is used to determine the theoretical frequency with which certain size-groups ought to appear. The two tests differ further in that the "Chi-squared" test can be applied to all the data representing a curve as well as to individual points on such a curve.

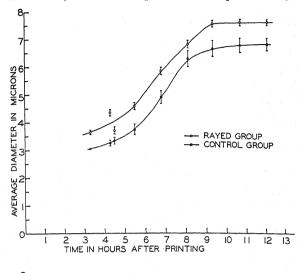

If the data which have been obtained in the work described can be shown to be significant by each of these three tests, there can be very little doubt that the effects of stimulation as they have been described are indeed real. It is therefore of great interest to apply each of these tests separately.

Table 2. Binomial law test.

Group		n	m	P's
A		7	0	.008
В	,	7	0	.008
C		9	0	.002
D		12	0	.00028
E		11	0	.00049
F		12	2	.016

н		5	0	.031

In table 2 are shown the results of applying the binomial law to the sign of the differences for a given sample of data.

The application of "Student's" t-test, and, in some cases, of the "Chi-squared" to a representative

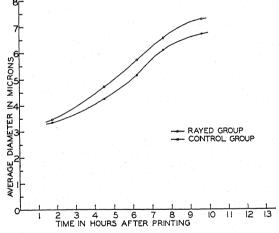

Fig. 3 (above). Fig. 4 (below).

sample of data are shown in tables 3, 4, 5, 6, 7, 8, 9, and 10. Here are listed the averages of eight spore groups at different times of culture, together with the averages of their controls, and the results of the t-test and in some cases of the "Chi-squared" test. The results of applying the "Chi-squared" test to the whole curve is also shown in some cases.

As a basis of comparison, three control groups have been divided arbitrarily into two parts and the t-test has been applied to these two groups, which were subjected to the same experimental conditions. The results are shown in table 11. Plots of the data shown in table 5 and table 10 are shown in figures 3 and 4.

It will be seen that, as shown by these three tests, the data are definitely significant, and the stimulation effects described are therefore confirmed.

The energies of cathode rays required to produce these stimulative effects were in general low, ranging from 1.5 to 3 kv. Such energies are no more than sufficient to propel the electrons through the cell wall and into the outer cytoplasm. The spherical, centrally-placed nucleus can hardly be involved. It follows that the stimulative effects which have been observed cannot be due merely to the fact that less hardy spores were completely killed, leaving only a sturdier population to grow, since cathode rays of these energies do not kill except in high density beams. The survival ratio of the irradiated material under these conditions may actually be as high as 120 per cent, as shown in table 12, giving data of the survival values for Aspergillus at 1.5 kv., 2 kv., and 3 kv.

cations may be primarily responsible for the change. It may be that a change in permeability of the cell wall is involved, resulting in a more ready absorption of water when the cell is "planted" on moist agar. More likely, there is an osmotic unbalance set up within the cell, caused by the large number of ions released within its substance, which may tend to draw water in through the cell membrane. It is also possible that some alteration of stored food material within the cell may have taken place which may make it more immediately usable in cell metabolism. Other explanations could doubtless be suggested.

#### SUMMARY

We have definitely been able to show that, when irradiated with cathode rays of certain energies and densities and subsequently cultured on potato-maltose agar, spores of the Ascomycete fungus Aspergillus niger are definitely stimulated in growth. Earlier signs of swelling, more rapid swelling, a larger average size at any given time, and a higher percentage of production of germ tubes have all been found in the irradiated samples as compared with controls.

A very large volume of data has been obtained in this connection, and three statistical tests of significance have been separately applied to it—the bino-

 ${\bf Table~12.~Survival~ratio~for~various~dos ages.}$

121.8	108.2	110.6	98.6		

We can only speculate at this time as to the cause of this stimulative effect. Cathode rays, like ultraviolet and X-rays, dissipate their energy by ionization, but differ from those radiation agents in that their energy is lost over a much shorter range per electron than per quantum for X-rays or ultra-violet. There is little doubt that at the energies which we have used in this work by far the greatest portion of ionization was concentrated in the spore walls of the cells, extending to the membrane and part of the cytoplasm. The nucleus cannot be directly involved. It therefore seems probable that extra-nuclear modifi-

mial law, "Student's" t-test, and the "Chi-squared" test. The data have been shown to be significant by all these tests.

These stimulative effects are observed only at relatively low cathode ray energies, of the order of from 1.5-3 kv. No definite explanation of the effect can be attempted at present. Some suggestions have been made.

# THE FORCES CONCERNED IN THE INTAKE OF WATER BY TRANSPIRING PLANTS <sup>1</sup>

## Paul J. Kramer

THE ABSORPTION of water is not an entirely independent process, but is one of several interrelated processes comprising the general field of plant water relations. The rates of transpiration, water conduction, and all the numerous other processes in which water plays a vital rôle are conditioned, at least in part, by the rate and amount of water absorbed through the roots. The rate of absorption, on the other hand, is affected by the rate of water loss, chiefly in transpiration, and the amount of water in the soil, its concentration, and its temperature. A complete discussion of the factors involved in water absorption requires some consideration of the structure of the roots, the laws governing the water relations of individual cells and those governing soil moisture relations. The present discussion will be confined to a consideration of the nature and origin of the forces operating to cause movement of water from the root hairs and epidermal cells across the intervening mass of living cells and into the xylem vessels.

Many discussions of the absorption of water by plants tend to stress the importance of the osmotic or secretory activity of the root cells but neglect the importance of the forces originating in the tops. It should be emphasized that the forces bringing about the intake of water originate not only in the roots but also in the shoots. In other words, some water is absorbed as a result of forces developed in the physiologically active root cells, but water is also absorbed because of forces developed in the tops by transpiration and transmitted to the roots.

During periods of low transpiration and abundant soil moisture, absorption by the roots often tends to

<sup>1</sup> Received for publication September 11, 1939.

exceed transpiration, resulting in the development of a positive hydrostatic pressure or "root pressure" in the xylem vessels. Since this type of absorption occurs only in the presence of physiologically active, living cells in the roots, it is frequently termed "active absorption" (Renner, 1915). The mechanism responsible for active absorption and the associated root pressure phenomena has not been satisfactorily explained, but it is usually regarded as some sort of osmotic phenomenon. Heyl (1933) after reviewing the extensive literature on the subject concluded that active absorption is an electro-osmotic process dependent on energy supplied by respiration of the root cells, a view also advanced by Lund (1931). Another explanation originated with the work of Atkins (1916) who suggested that root pressure is caused by diffusion of water from the very dilute soil solution across the cortical cells into the relatively more concentrated solution existing in the xylem vessels. Priestley (1922) believed that the endodermis, rather than the entire cortex, probably acts as the differentially permeable membrane. Kramer (1932) showed that water will diffuse through a thick, multicellular membrane of high osmotic pressure separating pure water from a sugar solution having an osmotic pressure much lower than that of the cells of the membrane. It was thus demonstrated that the cortex is capable of functioning as a membrane in the manner suggested by Atkins. None of these investigators was able to explain how a sufficiently high concentration of salts can be maintained in the xylem vessels to keep such a mechanism operating. Crafts and Broyer (1938) have suggested that the gradient of decreasing O2 and increasing CO2 existing from epidermis to stele in roots favors a higher level of activity in the cortical cells which are well supplied with oxygen than in the living cells of the stele. The cortical cells, therefore, are able to absorb salts at a comparatively high rate, but as the salts diffuse inward to the stele they are lost to the xvlem because the cells of the inner cortex and stele with a limited supply of oxygen and lower activity are unable to retain as high a salt concentration as the better aerated outer cortical cells. This would explain the maintenance of a sufficiently high concentration of solutes in the xylem to cause inward diffusion of water and perhaps root pressure. This scheme is complicated by the observations of Grossenbacher (1938, 1939) that cyclic variations in root pressure occur independently of any changes in temperature or light and are not related to variations in root respiration. Skoog, Broyer, and Grossenbacher (1938) have shown that the application of auxin to pea and sunflower seedlings stimulates exudation. This effect apparently is produced through the mechanism responsible for the diurnal periodicity in exudation, at least in sunflower. Possibly the diurnal variations actually occur in the metabolic process responsible for maintaining a supply of solutes in the xylem, and this in turn causes variations in exudation. These observations are difficult to reconcile with any theory based solely on a simple osmotic mechanism, and apparently we must still regard active absorption as incompletely explained.

The situation in the xylem of freely transpiring plants seems to be quite different from that in the xylem of slowly transpiring plants. During periods of moderate to rapid transpiration or low soil moisture, transpiration tends to exceed absorption, and positive pressure or exudation from cut stems cannot be demonstrated. On the contrary, water is usually absorbed through the cut surfaces of stumps of detopped plants, indicating that the water in the xylem is under reduced pressure or even tension. Removal of water from the xylem of the leaves by the mesophyll cells causes a reduced pressure or pull which is transmitted through the xylem to the roots, causing the movement of water from the surrounding living cells into the xylem. This movement occurs in part because decreasing the pressure on the water in the xylem, or placing it under tension, reduces its diffusion pressure. This increases the diffusion pressure deficit of the water in the xylem as compared to that of the water in the surrounding cells and in the soil. A gradient of decreasing vapor pressure and increasing diffusion pressure deficit is thus produced, along which water will diffuse from soil to xylem (Meyer and Anderson, 1939, p. 234 and 277). When an appreciable tension exists in the xylem, it seems possible that most of the water intake occurs as a mass flow along the gradient of decreasing pressure from soil to xylem. A gradient of less than one atmosphere, produced by a vacuum pump, greatly increases the intake of water, as has been shown by Renner (1929) and by Kramer (1932), and as is shown later in this paper. Under more extreme conditions the tension on the water in the xylem probably frequently exceeds the osmotic

pressure of the root cells, and the water in the cells also passes into a state of tension. At such times the "pull" of the transpiration stream presumably extends to the outer surfaces of the epidermal cells and is directly effective in bringing about water intake. During periods of rapid transpiration the absorption of water is determined principally by the rate of transpiration, and water intake is probably largely or entirely independent of the physiological or osmotic activity of the root cells. It has, therefore, been termed "passive absorption" by Renner (1915).

The importance of transpiration in bringing about the absorption of water was recognized even by some of the earlier physiologists. Hales (1727) carefully investigated the pressure with which water exuded from cut stems and measured the volume exuding but found that during the summer when transpiration was highest no exudation occurred. He believed that the loss of water in transpiration brought about the ascent of sap and stated, "And by the same principle it is, that we see in the preceding Experiments plants imbibe moisture so vigorously up their fine capillary vessels; which moisture, as it is carried off in perspiration (by the action of warmth), thereby gives the sap vessels liberty to be almost continually attracting of fresh supplies, which they could not do if they were fully saturate with moisture: . . . ." One might infer from these comments that Hales believed that transpiration was responsible for the conditions causing the intake of water. Sachs (1875, pp. 612-613) stated that root pressure could be of little importance in the ascent of sap, because when transpiration is rapid, water is absorbed by freshly cut stumps instead of exuding from them. Furthermore he found that the volume of water lost in transpiration from a leafy shoot always exceeded the volume of water exuding out of the stump from which the top had been removed. "From all this it still remains in doubt whether in such cases the contents of the cortical cells of the roots must not be left altogether out of consideration, since it is possible that the suction of the cell-walls merely, due to imbibition or surface action, reaches as far as the surfaces of the roots." It is clear that Sachs thought that the pull of transpiration, which he mistakenly believed to act largely through the cell walls, might bring about the absorption of water independently of any activity of the protoplasts of the root cells. Pfeffer (1900), who contributed much to our knowledge of osmotic phenomena, is even more explicit. Speaking of the pull of transpiration, he says (pp. 211-212), "By this backwardly transmitted suction the water in the roots is drawn into the vascular conducting channels, and at the same time the conditions necessary for fresh absorption from the soil outside are created by the agency of the cortex and by means of the root-hairs. No one-sided pumping action of the cortical cells is necessary for such absorption though if any does actually occur, it naturally aids and accelerates the latter. . . . That the consumption and removal of water by an organ should directly cause

absorption.

a fresh supply to be drawn in is a highly advan-

tageous arrangement. . . ."

Dixon (1910) stated that the tension developed in the water conducting system as a result of transpiration was transmitted to the roots and caused the intake of water by transpiring plants. He suggested that water might be regarded as moving through the plant along a gradient of decreasing vapor pressure from the soil to the parenchyma cells of the leaves. Renner (1912b) early distinguished between the absorbing forces developed in the roots and those developed in the top. Later Renner (1915) applied the

term "active absorption" to water intake brought about by forces developed primarily in the roots and "passive absorption" to water intake brought about by the effects of transpiration. Livingston (1927) stated that the rôle of the osmotic forces and vital activities of the root cells in water intake had been greatly overestimated and emphasized the importance of the physical forces resulting from transpiration in bringing about water intake. Shull (1930)

believed that the tension in the water in the xylem of transpiring plants extends to the adjacent, living cells, causing movement of water from these cells into the xylem. In his opinion a gradient of water deficits is thus produced across the roots of transpiring plants, causing the intake of water.

In spite of these repeated assertions that the forces bringing about water intake by transpiring plants originate principally in the top, we still find writers emphasizing the osmotic properties of the root cells and the possible importance of root pressure, while more or less ignoring the probable importance of passive absorption. Possibly this is because a complex explanation of water intake by physiological absorption is more intriguing than a simpler explanation based largely on physical absorption. More probably it is because quantitative comparisons of the amount of water absorbed by the two mechanisms have seldom been made. In order to better evaluate the relative importance in the water economy of the plant of these two absorption mechanisms, a comparison was made of the amounts of water entering the plant by active and by passive

EXPERIMENTS AND RESULTS.—Experiments were performed on coleus (Coleus blumei Benth.), hibiscus (Hibiscus moscheutos L.), balsam (Impatiens sultani Hook.), sunflower (Helianthus annuus L.), and tomato (Lycopersicum esculentum Mill.). The plants were grown in four-inch pots in loam soil, which was wetted to approximately the field capacity at the beginning of each experiment. The pots were placed in metal containers which were covered with oil cloth to prevent evaporation and placed on a sunny bench in the greenhouse or out-of-doors. The transpiration rates were determined by weighing the plants in their containers. After determining the rates of transpiration for two or three hours, the tops were cut off about three cm. above the soil, and graduated pipettes were attached by means of rubber tubing and grafting wax. Enough water was placed in the pipettes to make the meniscus easily visible, and the volume of liquid absorbed or exuded was observed at quarter- or half-hour intervals. The plants were growing vigorously, the root systems were in excellent condition, and it is believed that the rates of exudation were as high as could be expected from plants of the size used. The results are shown graphically in figure 1. The rates of transpiration of the tomatoes are the average for six plants for two successive hour periods near the middle of bright days. The rates of exudation are also averages of six plants. The data for sunflowers represent the average of eight plants, and the exudation data were obtained later in the day from the same plants used for the transpiration experiment. It will be observed that the rate of exudation of the tomatoes amounted to only 3.6 to 5.4 per cent of the maximum rates of transpiration recorded, while that of sunflowers was less than 1 per cent of the rate of transpiration. The data for sunflowers represent the rate of exudation for an hour period beginning two hours after the conclusion of the transpiration measurements. At

<sup>&</sup>lt;sup>a</sup> A minus sign indicates absorption of water through the stump instead of exudation from it.

this time two of the eight plants were still absorbing water instead of exuding it from the stumps. The rate of exudation of tomato was approximately doubled by attaching the tomato root systems to a vacuum pump and lowering the pressure until a gradient of 64 cm. of mercury existed from soil to the surfaces of the cut stems. The use of the vacuum pump increased the exudation of water from the sunflower about eightfold. As much water was obtained under vacuum from those sunflower root systems previously showing absorption through the cut surfaces as from those previously exuding freely.

A series of experiments was performed to study the rate of exudation from root systems following a period of rapid transpiration. A group of plants growing in pots of soil wetted to approximately the field capacity was allowed to transpire until noon on a sunny day. The tops were then removed, pipettes attached to the stumps, and the behavior of the plants was then observed for a few hours. The results for a group of six tomato plants are given in detail in table 1 and are shown graphically in figure 2 as algebraic averages of the six plants. The shoots were slightly wilted when removed, indicating that transpiration was probably exceeding absorption as usually occurs on bright days (Kramer, 1937). About one-half hour was required to attach the pipettes and begin measurement of exudation. During the first half hour of measurement water was absorbed through five of the six stumps. During the second half hour four root systems absorbed water and two exuded water, while during the third period three root systems showed exudation and three absorption. In the fourth half hour only one root system absorbed water, but it was not until the sixth period that water was being exuded from all six stumps. Later these root systems were attached to a vacuum pump, and the rate of water movement was found to be 3.5 times as great under a pressure gradient of 64 cm. of mercury as under atmospheric pressure.

The results of six experiments are summarized in table 2. Considerable difference exists between the behavior of the plants in the different experiments. Exudation reached almost its maximum in the first half hour in coleus, but not until the fourth half hour

in experiment two with tomato. In the experiments with hibiscus and balsam and the first experiment with tomato absorption occurred for a half hour to one and one-half hours after removing the shoots. Absorption ceased and exudation then began in hibiscus and tomato, but absorption continued in balsam until the soil was watered. These differences in behavior are evidently related to variations in soil moisture, rates of transpiration, and size of water deficit in the plants. In several experiments with tomato and sunflower it has been observed that if the tops of plants in moderately dry soil are removed, no exudation occurs until the soil is watered. This is sometimes true even though the shoots are not visibly wilted and the soil is certainly well above the wilt-

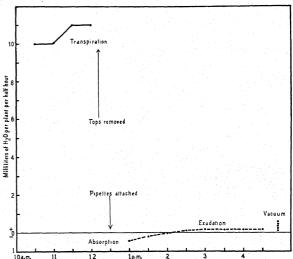

Fig. 2. Behavior of transpiring tomato plants following removal of tops. Note that the roots absorbed water through their stumps for over an hour after removal of the tops. The rate of water movement through the same root systems attached to a vacuum pump was 3.5 times the rate of exudation. The plants were growing in soil kept near its field capacity.

ing percentage. Probably the most significant fact to be obtained from table 2 is that exudation was always less than two per cent of transpiration.

Table 2. A comparison of transpiration and exudation. All rates are in ml. of  $H_2O$  per plant per half hour. The rates of exudation are for successive half-hour periods following removal of tops. The percentage relation is for the rate of transpiration during the last hour before removal of tops.

<sup>&</sup>lt;sup>a</sup> A minus signs means absorption of water by the stump instead of exudation from it.

Discussion.—The data presented here are representative of those obtained in experiments of this type. The rate of transpiration may vary widely with varying atmospheric and soil moisture conditions, while the rate of exudation seems to depend largely on past treatment and on soil moisture, aeration, and temperature. The general trend of these results is that which would be expected by physiologists familiar with this field of plant water relations. The principal new feature is the comparison of quantitative data on water intake of similar plants under several conditions.

The results obtained indicate that the rate of exudation from root systems of recently detopped plants amounts to only a small percentage of the water loss from the same or similar plants under conditions favorable to transpiration. If the rate of exudation is accepted as a measure of the rate of active absorption by a transpiring plant, then active absorption supplies a negligible amount of the water required to replace that lost in transpiration. It has been claimed, however, that we cannot evaluate the importance of active absorption in this manner because we do not know that it is proceeding at the same rate in a detopped plant as in an intact one. According to this view, the rate of active absorption or exudation of water into the xylem may have been much higher in an intact transpiring plant than it is in a root system from which the top has been removed. Consideration of the possible mechanisms which might be involved in active absorption gives no reasonable basis for such a belief. Investigators from Hales to the present writer have found that exudation frequently does not occur from the stumps for some time after removing the tops of freely transpiring plants. It seems highly improbable that if exudation or secretion of water into the xylem had been occurring during transpiration it would cease as soon as the top is removed, only to be resumed after an hour or two. It is the more doubtful since removal of the tops of slowly transpiring plants is immediately followed by exudation of water from the stumps.

The only possible method of measuring the rate of active absorption in intact plants seems to be by measuring the rate of guttation. Guttation is supposed to be caused by the same mechanism causing root pressure, and its occurrence, therefore, should be an indication of the occurrence of active absorption. Guttation occurs when conditions are favorable for absorption of water, but unfavorable for transpiration. If transpiration is stopped by placing a plant in a saturated atmosphere, guttation does not begin immediately. The behavior of guttation supports the view that active absorption may not occur in rapidly transpiring plants. While no quantitative comparisons are available, the volume of water exuding during guttation would amount to only a small percentage of the volume needed to replace that lost in transpiration.

It is often supposed that though active absorption may not be very important in transpiring plants, it does supplement physical absorption. It is probable, however, that little or no active absorption is occurring in the roots of many rapidly transpiring plants. The fact that the root systems of such plants often absorb water through the stumps for an hour or more after the tops are removed indicates that the root cells were not turgid when the tops were removed. It seems doubtful if any of the suggested mechanisms for secretion or osmotic movement of water into the xylem could function unless the cortical cells adjacent to the stele were turgid or at least had a diffusion pressure deficit lower than that of the contents of the xylem. If these cells were turgid, root systems of small plants in moist soil could not absorb one or two ml. of water through the surface of the stump after removal of the tops. Evidently the living cells of the roots absorb water from the xylem vessels, if it is supplied to the cut surfaces, and from the soil, if it is not too dry, until they are turgid. It is probable that only after the cells become turgid that active absorption can begin, resulting in movement of water into the xylem and its exudation from the open ends of the vessels at the stump. The writer has observed a number of instances in which no exudation occurred within 12 hours after removal of the tops, but then began within a few minutes when the soil was watered. This occurred with plants which were little or not at all wilted at the time of detopping and which were in soil certainly above the wilting percentage. This suggests that the maximum diffusion pressure deficit which can be developed in the roots of detopped plants may be lower than the maximum diffusion pressure deficit which can be developed in the roots of intact, transpiring plants. Kennedy and Crafts (1927) found that when the tops of rapidly transpiring morning-glory plants were removed, eosin and various toxic substances would often penetrate several feet into the roots and stain or kill them. The penetration was deepest and most rapid in dry soils and following periods of rapid transpiration. Penetration also occurred in roots of plants grown in water culture when exposed to the sun, but not if shaded prior to removing the shoots. It was suggested by Romell (1918) and by Köhnlein (1930) that the tension resulting from transpiration stimulates the root cells, causing increased passive absorption during periods of rapid transpiration. Köhnlein suggested this because his results indicated that the improbably high force of 20 to 73 atm. would be necessary to bring about the intake of sufficient water to supply a transpiring sunflower plant. His experimental procedure consisted of determining the transpiration rate of a plant, removing the top and attaching a vacuum pump, and determining the water intake with a given pressure gradient. From these data he calculated the root suction which must have been exerted to replace the water lost in transpiration.

In the experiment on which figure 2 is based the transpiration rate averaged 20 ml. per plant from 10 to 11 a.m. The rate of water movement through the root systems under a pressure gradient of 640 mm. of mercury averaged only 0.6 ml. per hour. On this basis a pressure gradient of about 28 atmospheres would have been required to supply the water needed to replace that lost in transpiration. Renner (1912a, 1929), using this and other methods, found somewhat lower forces necessary, but also decided that the values so obtained were improbably high and that the methods probably were unsatisfactory.

It is likely that the calculated pressure gradients were higher than necessary, because Brewig (1936) has shown that as the rate of transpiration increases the area of the root through which water is absorbed also increases. At low rates the absorbing zone is comparatively short, but as transpiration increases the tension in the vessels presumably also increases. This increases the steepness of the diffusion pressure deficit and pressure gradients, and the absorbing zone is extended toward the base of each root, greatly increasing the absorbing surface. This view is also supported by the work of Rosene (1937). It is probable, however, that fairly large pressure gradients are frequently developed across the cortex, since the cortical cells seem to offer considerable resistance to the movement of water (Kramer, 1938). Ordinarily a gradient of a few atmospheres probably exists, but if absorption lags much behind transpiration, a gradient of 100 atmospheres or more might possibly be developed in some plants (MacDougal, Overton, and Smith, 1929).

Consideration of the possible mechanisms bringing about active absorption and exudation into the xylem reveals no reason why any of the suggested mechanisms for active absorption would not function as well, as least for a few hours, in a detopped root system as in that of an intact plant. Whatever the exact mechanism, the necessary energy is probably supplied by the respiration of the cortical cells. This would simply require that they be supplied with sufficient food and oxygen to maintain normal physiological activities. That these conditions are fulfilled is probable, since a comparatively high rate of exudation is often maintained for several hours or even days after the tops are removed. The data of Grossenbacher (1938), for example, indicate that a comparatively high root pressure was maintained for at least a week by sunflower root systems, and Hoagland and Brover (1936) found that ion absorption by excised barley roots continued at a high rate for many hours.

Boonstra (1935) attempted to determine whether or not a positive pressure might exist in the roots of transpiring peas even though decreased pressure or tension existed in the stem. He sealed the plants into potometers in such a manner that any change in volume could be observed when the roots were severed from the stems. In some experiments part of the root projected above the stopper of the potometer so the lower part of the root was severed from the upper part. In every instance a sudden increase in absorption occurred immediately after cutting the roots, indicating that the pressure in the xylem of the roots was below atmospheric pressure rather than above, and that absorption rather than exudation had occurred through the cut surfaces.

The best way to determine the relative importance in water intake of the forces developed in the roots and those developed in the shoots probably is to separate the roots from the shoots. Renner (1912b) performed such experiments and decided that the absorbing power of the roots of transpiring plants is chiefly produced by the suction of the leaves. It was found by Kramer (1938) that the rate of absorption of transpiring sunflower and tomato shoots grown in water culture was significantly greater after removal of the root systems than it was with the root systems attached. Apparently instead of "pumping" water into the plant, the cells of the roots offered so much resistance to water movement that they were actually retarding absorption. This resistance to water movement is much greater at low temperatures.

It is known that exudation from the stump can often be stopped by placing the root system in salt or sugar solutions. Renner (1929) found that a reversal of water movement occurred in dilute solutions of sucrose and KNO<sub>3</sub>. The writer (1932) also found that exudation was stopped by dilute sucrose solutions. Tagawa (1934) carefully investigated the

relation between concentration of the surrounding solution and rate of water intake. He found that root systems of beans could not absorb water from sucrose solutions with an osmotic pressure of two atmospheres, but intact transpiring plants absorbed water from solutions with an osmotic value up to 14.6 atmospheres. He concluded that in these experiments the shoots developed an absorbing force of more than 12 atmospheres, the roots only 1.9 atmospheres.

A further reason for doubting that active absorption or root pressure phenomena play an essential rôle in the intake of water is the fact that it apparently never occurs in the gymnosperms. It would be very surprising if such a process were essential in one group of plants, yet not even occur in another group which is so similar in many respects. If we could learn why root pressure does not exist in gymnosperms, we might be better able to explain its oc-

currence in angiosperms.

It has sometimes been claimed that the metabolic activity of the root cells must be an important factor in the absorption of water because water intake is materially reduced by low temperatures and by poor aeration, both of which are known to reduce the rate of cell metabolism. It appears possible, however, that the physical effects of low temperature and poor aeration are sufficient, by themselves, to explain the decreased absorption of water. In experiments on root systems attached to a vacuum pump it was found that water intake through living roots at 2°C. was reduced to about 20 per cent of the rate at 25°C., and the rate of water intake through dead roots at 2°C. was about 50 per cent of the rate at 25°C. (Kramer, 1939). Low temperature increases the viscosity of water and decreases the permeability of the cell membranes, thus greatly increasing the resistance to water movement. This causes a large decrease in water intake at low temperatures which seems to be independent of the effects of low temperatures on cell metabolism. It has also been found that a high concentration of carbon dioxide causes a 30 to 50 per cent reduction in water intake through living root systems attached to a vacuum pump, a reduction which apparently may be ascribed to decreased permeability of the roots rather than decreased physiological activity of the root cells.

Although active absorption and root pressure apparently do not occur at all in some species and probably are not essential to any species, they may play a certain part in refilling xylem vessels with water which have become air-filled during periods of rapid transpiration. It is well known that the water content of many deciduous trees reaches a minimum during the late summer and gradually increases to a maximum in the autumn and winter (Gibbs, 1935). Perhaps this is more or less related to root pressure phenomena, though other explanations are possible. Seasonal variations in water content are less pronounced in conifers, possibly because they do not have root pressure.

While active absorption and root pressure are of common occurrence in many plants, it appears that

there is no conclusive evidence that they play either an essential or even an important part in the water relations of such plants. During times of rapid transpiration or low soil moisture, active absorption probably does not occur at all, and water intake is brought about by forces set in action by the loss of water in transpiration. At such times water may be said to be absorbed through the roots rather than by the roots. The occurrence of active absorption and the accompanying root pressure phenomena is possibly merely a fortuitous result of the root structure and of the manner in which salts are absorbed from the soil. Since it can only be studied in detopped plants, or possibly by observing guttation in entire plants, it is perhaps impossible to prove that active absorption or forces developed in the roots have no important rôle in the absorption of water. These experiments have shown, however, that the forces which have been measured and discussed by earlier workers as root pressure or exudation phenomena are wholly inadequate to supply the water requirements of a transpiring plant.

#### SUMMARY

The relative importance of passive absorption caused by forces produced in the transpiring shoots and of active absorption caused by the osmotic or secretory activity of the root cells has often been debated. A quantitative comparison of the amounts of water entering plants by active and by passive absorption was therefore made in order to better evaluate the relative importance of the two mechanisms.

A comparison was made of the rates of transpiration of potted coleus, hibiscus, balsam, sunflower, and tomato plants with the rates of exudation from the stumps of the same or similar plants following removal of the shoots. The rate of water movement through detopped root systems attached to a vacuum pump was also determined.

It was found that the rate of exudation from detopped root systems was only one to five per cent of the rate of transpiration from similar intact plants.

When the tops were removed from freely transpiring plants, frequently no exudation occurred, but instead water was at first absorbed through the freshly cut stem surfaces, and exudation began only after one-half to two hours. In some experiments exudation did not begin until the soil was watered.

Several previous investigations have shown that intact plants can absorb water from much more concentrated solutions than can detopped root systems. This seems to indicate that the greater part of the forces causing the intake of water originate in the transpiring shoots rather than in the living cells of the roots.

Root pressure has never been observed in the gymnosperms, and it is probable that active absorption never occurs in that group. It seems doubtful if a process which never occurs in one division of the seed plants would be essential in another group which is otherwise quite similar physiologically.

It is concluded that active absorption, as made evident by exudation and root pressure phenomena,

is wholly inadequate to supply the water requirements of transpiring plants. It is possible that active absorption does not even supplement passive absorption in rapidly transpiring plants, because none of the suggested mechanisms for physiological absorption would operate unless the cells of the roots are turgid. Possibly root pressure is a fortuitous result of the root structure and of the manner in which minerals are absorbed by certain plants.

Most, and possibly under some conditions all, of the water absorbed by transpiring plants is absorbed as a result of forces set in motion by the loss of water in transpiration. Removal of water in transpiration decreases the pressure or causes tension on the water in the xylem, producing a gradient of decreasing pressure and increasing diffusion pressure deficits along which water moves by mass flow and to some extent by diffusion from the epidermis to xylem. The roots act as passive absorbing surfaces in such a mechanism, but healthy growing root systems are very important because extension of roots through the soil continually makes available new supplies of moisture.

# DIFFERENTIAL GROWTH IN PLANT TISSUES. II. A MODIFIED AUXIN TEST OF HIGH SENSITIVITY 1

Kenneth V. Thimann and Charles L. Schneider

When elongating stems or other organs are slit longitudinally and placed in auxin solutions, the halves curve toward one another, as was first shown by Went (1934). In the course of an analysis of this and similar reactions, it was pointed out (Thimann and Schneider, 1938) that Avena coleoptiles are among the large number of objects which respond well. The present paper will describe a modification of the procedure, using Avena coleoptiles, which enables auxin to be quantitatively determined at very much lower concentrations than has previously been possible. Certain of the theoretical implications of this reaction will also be considered.

THE "QUARTERED COLEOPTILE" TEST.—Procedure.—Avena coleoptiles, from plants about 3 cm. long grown in the dark-room on wet filter-paper with their roots in tap water, are decapitated at 3 mm. from the tip, slit longitudinally downward for a distance of 2 cm., turned through 90°, and again carefully slit downward for the same distance. We have also used a special cutter (fig. 1), consisting of

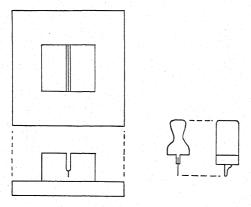

Fig. 1. Tool for quartering coleoptiles. Top and front view of holder and front and side view of cutter. See

CUTTER

HOLDER

text.

two pieces of brass, one a holder with a groove 1.5 mm. wide (in the bottom of which the coleoptile is laid), the other a cutter consisting of a brass handle with a guide 1 cm. long which just fits into the groove and which has inserted into it a fragment of razorblade. This blade is centered during the cutting operation by means of a very fine slit (about 0.2 mm. wide) at the base of the groove; in this slit the blade just slides freely without touching the bottom. The intact coleoptile, with leaf in, is slit for a distance of 1.5 cm., terminating a few mm. below the tip, then

<sup>1</sup> Received for publication September 16, 1939. <sup>2</sup> Made for us by Mr. J. A. Westgard of these laboratories. turned through 90° and slit again. The tip and leaf are subsequently removed. The resulting quartered coleoptiles are placed in a Petri dish of the solution to be tested. After 24 hours at 25° in the darkroom the curvatures are estimated to the nearest 10° either with a 360° protractor, or (with a little practice) by eye, and the mean taken. In distilled water the quarters curve outward through a very large angle—of the order of 250°, though varying somewhat from test to test. In dilute auxin solutions this outward curvature is reduced, and in higher concentrations the curvature becomes inward.

Sensitivity.—In the older procedure the coleoptiles were slit only once—i.e., halved. If we compare the curvatures obtained by quartering with those obtained by halving, a marked difference is observed. In indole-acetic acid, the halved coleoptiles show a definite decrease in outward curvature (the first step toward inward curvature) at 0.1 mg. per liter. This is also exemplified in figure 3 of Thiman and Schneider (1938). With the quartered coleoptiles, however, the very large outward curvature in water is slightly increased at about 0.00002 mg. per liter and shows decrease at concentrations of 0.0003 mg. per liter and above. In both methods

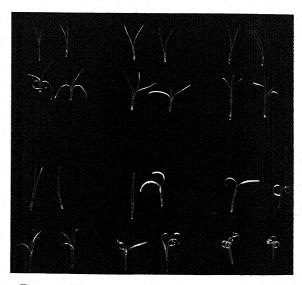

Fig. 2. Halved and quartered Avena coleoptiles after 24 hours in distilled-water auxin solutions of strengths: left to right, top, 0, 0.0016, 0.04; bottom, 0.2, 1, and 10 mg. per liter.

the concentration causing actual inward curvature is about the same.

The responses of halved and quartered coleoptiles are illustrated in figure 2 and shown quantitatively in figure 3, which is a mean of three complete experiments with indole-acetic acid.

As will be noted, the curve shows an inflection at about 0.05 mg. per liter. In some of the many experiments performed this inflection was still more marked, in others (e.g., fig. 5), it was practically absent. Such an inflection might suggest that two different effects are present—one causing actual inward curvature, which is essentially the same as with halved coleoptiles, and another causing decrease in the large outward curvature, which is completely missing from the responses of the halved plants. However, not only is there no direct evidence that the two effects are really different, but the comparison of different auxins (see below), and the considerations advanced in the discussion, strongly indicate that reduction in outward curvature and appearance of inward curvature are both part of the same phenomenon and merge continuously into each other.

In the standard Avena test, using agar blocks, the lowest concentration giving practically measurable curvature is about 0.01 mg. indole-acetic acid per liter of solution, which when mixed with an equal

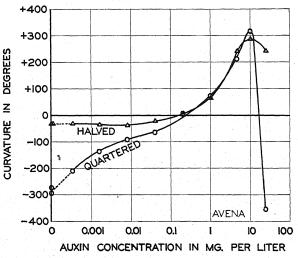

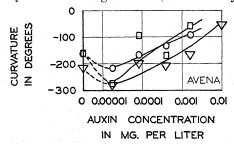

Fig. 3. Comparison of the curvatures of halved and quartered Avena coleoptiles in serial auxin dilutions.

volume of 3 per cent agar gives about 2°. With the deseeded test of Skoog (1937) or with Cephalaria seedlings (Söding, 1936), this lowest concentration may perhaps be decreased by as much as five times. The modified slit stem test on peas, described by Went (1939), responds to about the same concentrations as the standard Avena test. Thus the quartered coleoptile test gives easily measurable curvatures, say 50° less than that of the controls, at concentrations 30 times lower than those effective in the standard test and some six times lower than those effective in the deseeded and Cephalaria tests.

The suggestion may be advanced that the lowest effective concentration approaches the true relationship between the auxin and its substrate in the cell. In the case of decreased outward curvature, which is a response of the outermost tissue layers, it is a

simple matter to calculate the amount of auxin needed per cell. The average volume of the epidermal cell of the coleoptile is about 10<sup>-4</sup> mm.<sup>3</sup>, so that (assuming equal distribution of auxin inside and outside the cell) at a concentration of 3·10<sup>-4</sup> mg. per liter we have 3·10<sup>-14</sup> mg. auxin, or about 90,000 molecules, per cell.

The increase in outward curvature, due presumably to increased growth of the inner layers (see

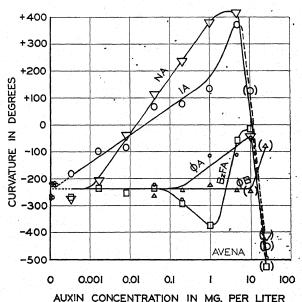

Fig. 4 (above). Curvatures of quartered Avena coleoptiles in very dilute auxin solutions. The three curves are

three separate experiments.

Fig. 5 (below). Curvatures of quartered Avena coleoptiles in serial dilutions of several synthetic auxins. IA, indole-3-acetic; NA,  $\alpha$ -naphthalene-acetic;  $\Phi$ A, phenylacetic; BzFA, benzofurane-3-acetic;  $\Phi$ B,  $\gamma$ -phenyl-butyric acids.

Thimann and Schneider, 1938), appears at still lower concentrations. In order to be certain of its reality a number of experiments were carried out with very low concentrations; these are summarized in figure 4. It will be seen that the inner layers respond to concentrations around 0.00001 mg. per liter, or one part in 10<sup>11</sup>, an excessively low figure. It is of interest to note that this corresponds with the concentrations found to promote root growth (cf. for instance Geiger-Huber and Burlet, 1936). If we assume that the cells do not accumulate auxin

and that their volume is the same as that of the epidermal cells, the minimal amount for a measurable effect would be 3000 molecules of auxin per cell.

Variation in results.—Most of the sources of error lie in the slitting process. Variation in length of the slit and in width of the quarters is hard to avoid. Twisting of the quarters may also result from confinement to the shallow layer of solution, but this can be easily detected and allowed for. The variation within one test can, of course, be treated statistically. Using four plants (16 curvatures) the probable error of the mean in the water controls is generally 10°-12°. If the probable error of the mean in the lowest auxin concentration is the same, then the probable error of the difference between the two is  $\pm \sqrt{12^2 + 12^2}$  or about  $\pm 17^{\circ}$ . In other words, to show minimal auxin concentration, the outward curvature should be reduced by 50°. This requires a concentration of 0.0003 mg. indole-acetic acid per liter (see figures 3 and 5).

Influence of vascular tissues.—Quartered coleoptiles in water or very low auxin concentrations frequently show two segments with strong outward curvatures (averaging 250°) and two with weak curvatures (averaging 150°). An example may be seen in the water controls of figure 2. In such cases it is invariably found that the vascular bundles are in the strongly curved segments (cf. fig. 6B). In a long series of tests with different concentrations of indole-acetic acid ranging from 0.00001 to 10 mg. per liter, the segments with the vascular bundles curved outward about 100° more, or inward about 100° less, than the others.

That the effect is not due to pressure against the bottom of the dish in the shallow layer of liquid may be shown by using very deep layers of aerated water, in which the bases of the quartered coleoptiles are fixed to glass pins, the whole coleoptile being thus immersed and the quarters free from the walls. The marked difference persists under these conditions.

The explanation of this phenomenon is probably very complex and will not be attempted here. The data in this paper are the averages of the "vascular" and "non-vascular" quarters throughout. Since the differences between these two are about 100° and show no trend with changing auxin concentration, the curves of concentration against curvature merely parallel one another.

Other influences.—The outward curvature of water controls is considerably smaller when tap water is used. In one experiment the controls in dis-

tilled water gave 217°, those in tap water 80°; in another experiment the values were 348° and 138°, respectively. Similarly, old distilled water which had been kept in soft glass carboys for about six weeks gave outward curvatures some 60° lower than those in fresh distilled water. It appears that the coleoptiles are sensitive to traces of some salt or salts.

This salt effect was tested over the whole range of auxin concentrations. In table I curvatures in solutions made up with distilled water are compared with those in solutions made up with tap water. The effect of the tap water decreases somewhat as the auxin concentration increases, although it is present throughout the range. The differences between curvature in auxin and curvature in the water controls, however, are consistently smaller when tap water is used

The outward curvature is also decreased when very small volumes of solution are used. In experiments with four coleoptiles in 20 cc. of distilled water, the curvatures were 293° and 324° (cf. data in fig. 3); with two coleoptiles in only 2 cc. in the same experiments, the values were 116° and 205° only. This effect has been observed on numerous occasions. It was first thought that certain salts, or possibly auxin itself, might have diffused into the water from the cut surfaces. To test this, two coleoptiles were placed in each of ten 2 cc. samples of distilled water for 24 hours; these samples of water were then combined to make one quantity of 20 cc., into which fresh coleoptiles were placed. The resulting curvatures were slightly, but not significantly, lower than those given in a new sample of distilled water. In another experiment the water in which quartered coleoptiles had been placed was extracted with ether and the extract tested for auxin content, but with completely negative results. Aeration of the 2 cc. volume also did not increase the curvature. It is thus difficult to ascribe the effect either to material diffusing from the coleoptiles or to oxygen deficiency. Whatever be the reason, this effect constitutes a limitation on the application of the quartered test to small volumes, since with the smaller outward curvature of the controls the sensitivity to the lowest auxin concentrations is somewhat reduced (see the experiment below).

Some applications of the method.—Comparison of different auxins.—The results obtained using serial dilutions of a number of auxins are shown in figure 5. The principal points to be noticed are: (1)

Table 1. Comparison of auxin curvatures of quartered coleoptiles in distilled water and tap water solutions. A plus sign indicates inward curvature; a minus, outward.

Table 2. Relative activities as determined by the quartered coleoptile test compared with those determined by other Avena methods.

	Quartered coleoptile test	Straight growth test	Standard Avena test (agar-curva- ture)
Indole-3-acetic acid	. 100	100	100
$\alpha$ -naphthalene-acetic acid	. 35	15	2.5
Phenyl-acetic acid		0.3	0.02
Benzofurane-3-acetic acid	. 0.03	0.1	0.02
γ-phenyl-butyric acid		0.06	0.005

indole-acetic acid is active at lower concentrations that any other compound tested (the concentrations giving outward curvatures were not included in these experiments), (2) the curve for a-naphthalene-acetic acid has a steeper slope than that for indole-acetic, and (3) benzofurane-acetic acid gives large outward curvatures at concentrations around 1 mg. per liter, which change to inward curvatures at about 5 mg. per liter. All these observations agree with those previously obtained with the slit pea-stem test (Thimann and Schneider, 1939), which suggests that they represent phenomena of general importance.

For each auxin studied, the range of concentrations causing inward curvature is continuous with that reducing the outward curvature. There is therefore no reason here to suppose that decrease in outward curvature is anything but the first step toward inward curvature.

The principal difference from the test with peastems lies in the much greater selectivity of the Avena coleoptiles-i.e., at low concentrations the differences between different auxins are relatively great. If as measure of activity we take the reciprocal of that concentration which reduces the outward curvature by 100°, the relative activities of the different auxins can be assessed. These values, expressed as percentage of the activity of indoleacetic acid, are listed in table 2, together with values obtained from other methods previously reported. It will be seen that the quartered test is about as selective as the other Avena methods. As already pointed out, a few comparative tests by several different methods, using a series of concentrations of different auxins, would serve to identify, with a fair degree of certainty, as unknown auxin with a known one.

Botanical tests.—The sensitivity of the quartered coleoptile to very dilute auxin solutions suggests its application to numerous problems of auxin distribution. Two examples may be given.

From the data in the literature on the production of auxin by coleoptile tips, it may be calculated that one tip, after cutting off, should set free into 2 cc. of solution a total amount of auxin roughly equivalent to 0.0002 mg. indole-acetic acid per liter. Hence two to four tips, placed in 2 cc. of water, should give enough auxin to produce significant curvature in the quartered test.

An attempt was therefore made to use the test to detect the auxin diffusing from a few coleoptile tips. Four quartered coleoptiles were placed in 2 cc. of water into which freshly cut *Avena* tips were introduced. Table 3 gives the mean of three such experi-

Table 3. Measurement of auxin production by Avena coleoptile tips and by Phaseolus nodules using the quartered Avena coleoptile test as assay method.

No. of tips or half-nodules:	0	2	4	8	16	32
Outward curvature for:						7
Coleoptile tips	116	111	129	54	55	44
Root nodules			133			

ments. A significant decrease of curvature is produced when eight or more tips are used. This effect can hardly be due to traces of salt diffusing from the tips, since far more of such material would be provided by the four quartered coleoptiles, with their long cut surfaces, than by the tips. The outward curvature of the water controls in these experiments is in any event already lowered by the volume effect mentioned above, so that the further lowering can safely be ascribed to the auxin coming from the tips. It is, indeed, because the water controls give curvatures lower than normal that two or four tips do not give the expected effect. However, it is satisfactory that the small amount of auxin produced even by eight tips when dispersed in 2 cc. of water should be so readily detectable.

A comparable experiment was made with root nodules of *Phaseolus vulgaris*. Nodules about 2 mm. in diameter were halved and varying numbers placed in 20 cc. of water. As table 3 shows, water in which four nodules were placed reduced the outward curvature by 63°, which is fully significant. Sixteen nodules (32 halves) are even more active than 32 tips. It follows that these nodules are at least as effective in auxin production as the coleoptile tip.

On the other hand, soil solution, made by shaking 80 grams of garden soil with 100 cc. of tap water and filtering, gave curvatures no different from those of tap water controls. The auxin content of such soil solution must therefore be extremely low.

MECHANISM OF THE CURVATURE.—Although it is now generally agreed that curvatures of the type dealt with here are caused by differences between the amounts of growth of which the inner and outer layers of the slit object are capable, it is not yet certain to what this difference in growth is due. According to the view previously put forward (Thimann and Schneider, 1938), the difference in growth is due to an inherent difference in sensitivity between the inner and outer tissues, while according to Went (1939) it is the result of the wounding process itself. Our own experiments are in agreement with those of Went, and also of van Overbeek and Went (1937), in showing that wounding does somewhat decrease the response of stem tissues to auxin. The effect of the wounding may therefore contribute to the cur-

Fig. 6. Three methods for slitting coleoptiles. A, halving; B, quartering; C, narrow strips with cuts on two of the strips at right angles to the plane of curvature. See text.

vature, but, as will be shown, it is improbable that it is an essential for it.

In the first place, Avena coleoptiles are hollow, so that when they are slit they have only a very small area of wounded surface. Yet they give inward curvatures of about the same magnitude and sensitivity as do pea stems, which have a much larger area of wounded tissue.

In the second place it must be remembered that inward curvature (i.e., bending toward the wound) is not the only phenomenon observed. Low concentrations of both indole-acetic and a-naphthaleneacetic acids cause increased outward curvature, and with benzofurane-3-acetic acid, from 0.2 to about 2 mg. per liter, this effect is extremely strong. Here the wounded side must be growing more than the outer intact side. It must be noted that these outward curvatures do not differ in their time relations from inward curvatures. This is shown clearly in figure 11 of Thimann and Schneider (1938) in which the outward curvature in 2 mg. per liter benzofurane-acetic acid takes about 15 hours, while inward curvature in I mg. per liter indole-acetic acid takes about 18 hours. Thus all the evidence is consistent with the view that this increased outward curvature is a true growth response.

The present experiments provide additional evidence as to the mechanism of the curvature. As the diagram, figure 6B, shows, the wounded surfaces of quartered coleoptiles are at an angle to one another, so that the influence which they can exert on growth is limited to that component in which they reinforce each other. In spite of this fact the magnitude of the curvatures is just as great as with the halved coleoptiles, while the sensitivity to low auxin concentrations is, of course, much greater.

In order to minimize the effect of wounding, coleoptiles were quartered so as to obtain strips having the cut surfaces parallel and thus with no component in the direction of the curving (see figure 6C). Such strips regularly curved inward in auxin of concentrations from 0.04 to 5 mg. per liter. To make such cuts with accuracy, however, is difficult on Avena, in which the coleoptile is only 1.2 mm. in diameter. More striking results were obtained with Zea Mays coleoptiles, which are much larger. In figure 7 camera lucida drawings of three such curvatures are shown. The sections show strong inward curvatures, although the two wounded surfaces remain almost parallel. These experiments confirm the view that the curvatures are essentially due to inherent differences in the response to auxin of inner and outer tissues, or, as Jost (1938) has expressed it, that the curvature is nastic rather than tropistic. The conclusions from Jost's experiments are in full agreement with those to be drawn from our own.

Some other points call for mention here. One arises from consideration of the geometry of a half-or quarter-cylinder such as a slit coleoptile. This

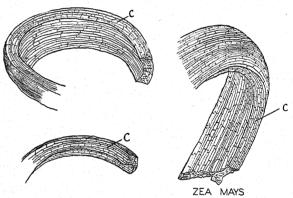

Fig. 7. Camera lucida drawings of strips of Zea Mays coleoptiles curving in auxin solution. The injured surfaces, C, have little or no component in the plane of curvature.

may be regarded as a trough or groove, and evidently the degree of longitudinal curvature will not be without effect on the degree of transverse curvature or "grooving." When rubber tubing is slit longitudinally and then bent, the groove will tend to become flattened irrespective of whether the curvature is "inward" or "outward." This flattening may be readily observed in outwardly curving slit coleoptiles, but it does not happen when the curvature is inward. Instead, the "grooving" generally becomes even deeper—i.e., the segment of tissue actively curves inward in cross section as well as in length. This indicates that auxin has some influence in promoting tangential as well as longitudinal growth and that this influence is different on the inner and outer tis-

<sup>3</sup> A similar experiment is reported by Went (1939), but he did not obtain inward curvature. In a number of trials our only failures have been when the strips were extremely narrow. In such very narrow strips the proportion of cells adjacent to wounded surfaces is very high, and thus the "damage effect" may perhaps become important enough to prevent much growth. However, other explanations are not excluded.

sues. It must be emphasized, however, that the increase in "grooving" is a relatively small effect and is not itself responsible for the curvature.

The difference between the behavior of the quartered and halved coleoptiles is evidently largely a mechanical one, because pea stems also show it. In figure 8 are compared the curvatures of etiolated Pisum internodes prepared by the two methods. The quartered sections show larger outward curvatures in water than do the halves, while the lowest auxin concentration which gives a significant decrease in outward curvature is at least ten times lower than with the halved sections. Evidently, as with Avena, when the material is only halved, the left-hand end of the curve is completely lost, and this is almost certainly due to the mechanical stresses inherent in the differently shaped cross section. For this reason it seems improbable that the lowest concentrations active in the halved test have any "stoichiometrical" significance.

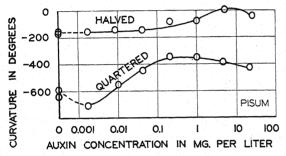

Fig. 8. Curvature of halved and quartered *Pisum* stems in serial auxin dilutions.

The same difference between the behavior of quartered and halved coleoptiles may be seen in the curvatures caused by acid. As is well known, acid solutions greatly increase the outward curvature. Figure 9 shows that here also the sensitivity to low concentrations of acid is greater with the quartered material. It may be noted that if the explanation of the acid curvatures given by D. Bonner (1938) is correct—i.e., that they are due to a setting free of the undissociated form of the auxin (i.e., the free acid) on the cut side—then it follows that the cut

side must have retained its ability to grow in response to the auxin set free. Bonner's calculations do not indicate a very great increase in the proportion of undissociated auxin on the cut side, yet the acid curvatures are very large. This also would not

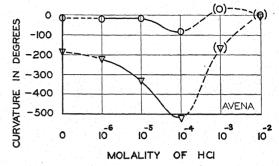

Fig. 9. Curvatures of halved (circles) and quartered (triangles) Avena coleoptiles in serial dilutions of HCl.

support the view that the wounded side has lost its sensitivity to auxin.

### SUMMARY

An assay method is described in which Avena coleoptiles are slit into four parts longitudinally and these slices allowed to curve in auxin solutions. The test is some thirty times as sensitive as the Avena test with agar and can detect concentrations of indole-acetic acid as low as 0.01 gamma per liter.

Various factors affecting the test are discussed, and some examples of its use for dilute auxin solutions and for comparison of different auxins are given.

It is pointed out that the increased sensitivity of the test is probably mainly to be ascribed to mechanical factors affecting the curving sections.

The essential features of the test support the view that curvatures of this type are due to inherent differences in the response to auxin of adjacent layers of tissue.

# TWO OCCURRENCES OF NATURAL PAPER FORMED BY ALGAE <sup>1</sup>

S. C. Bausor

RECENTLY MORELAND (1937) described an instance of the formation of natural paper by the matting and drying of algal filaments, mostly Tribonema, in fields inundated by the overflowing of the Atchafalaya and Ouchita Rivers in Louisiana. This spring two similar cases of the formation of natural paper from algal remains were discovered in temporary marshes, and in both instances the paper was made up predominantly of the alga Tribonema.<sup>2</sup>

On May 7, at the intersection of Crystal Street and Harrison Avenue in Harrison, New York, I came upon a swamp in which *Tribonema* was grow-

Another alga of filamentous organization was found in the marsh and also was incorporated into the paper. It was a much smaller filament  $(37~\mu \times 5~\mu)$  with relatively thick walls which were Tribonema-like. The dried paper was white with a grayish cast and rather soft to the touch when relatively free of débris. This swamp was revisited on June 3. It had dried up completely, and the whole area previously under water was now covered with a mat of algal paper (fig. 1).

On May 21, the writer visited a rather large temporary swamp in the Pocono Mountains near Analo-

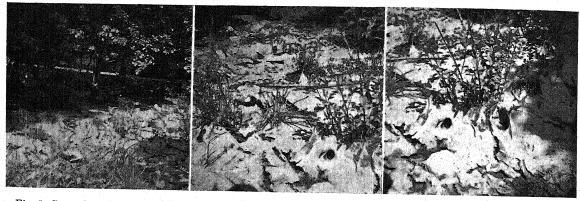

Fig. 1. General view of a portion of the dried up marsh at Harrison, New York, June 3 (left); paper covering the floor of the marsh (center); and a close-up of the algal paper on the floor and draping stubble (right).

ing luxuriantly. The swamp was drying up rather rapidly, and the algae which were left stranded along the edge of the marsh dried in paper-thin mats on the fallen leaves and other débris on the floor of the swamp. Twigs and stubble sticking up in the still-submerged portions caught masses of the algae as the level of the water became lower. Those exposed were in process of drying into sheets of paper.

Examination of the living algae and the paper showed conclusively that Tribonema bombycinum (Ag.) Derb. & Sol. was the predominant filamentous (fibrous) material in both. When treated with hot concentrated hydrochloric acid, the filaments of the algae and the fibers of the paper became separated into the H-shaped segments characteristic of Tribonema. When the algae and the paper were treated with a saturated solution of potassium hydroxide, the stratification and interlocking of the two portions of the wall became evident as the wall material swelled. The cells of Tribonema bombycinum averaged 63.3  $\mu$  in length and 13.3  $\mu$  in diameter, while the cells of the fibers in the paper after soaking were 51.8  $\mu$  in length and 14.0  $\mu$  in diameter.

Received for publication June 24, 1939.

<sup>2</sup> Specimens of the paper and the algae are deposited at the New York Botanical Garden and at the Field Museum of Natural History, Chicago. mink, Pennsylvania, in which natural paper was forming. This marsh was similar to the one at Harrison. Microscopic examination showed that the algal mass and the paper were predominantly Tribonema bombycinum. In addition, however, other algae of filamentous organization were found mingled with the Tribonema in both the paper and the living algae. Among the more abundant of these were a species of Zygnema, an unidentified filament containing aplanospores, and the blue-green alga Anabaena.

The formation of natural paper by the matting of interwoven fibers of *Tribonema* apparently is not an uncommon phenomenon and probably may be expected wherever a stagnant body of temporary water supporting a luxuriant growth of algae is subjected to rapid evaporation.

# ULTRA-VIOLET SPECTROPHOTOMETRY OF ZEA MAYS POLLEN WITH THE QUARTZ MICROSCOPE <sup>1</sup>

Fred M. Uber

QUANTITATIVE INTERPRETATIONS of data on the biological effects of ultra-violet radiation must usually be based on a knowledge of absorption by the organism involved. Information of this kind has been used most often in an attempt to correlate biological effects directly with the total energy absorbed. Less frequently, the important question of a screening effect has been the desideratum. Owing to the slight penetration of living matter by ultra-violet, one is ordinarily concerned with objects of microscopical size, at least in one dimension. Where the organisms are such as to be compressible into thin uniform layers, data can be obtained rather readily, as in the bacterial measurements of Gates (1930). Where single organisms must be subjected to measurement, the use of a microscope is indicated. In the latter category are the investigations by Vles and Gex (1934) on sea urchin eggs, by Baas-Becking and Ross (1925) and Albers and Knorr (1937) on chloroplasts, and the splendid work of Caspersson on the salivary gland chromosomes of Drosophila. Ultraviolet absorption spectra of microscopic preparations have also been studied by Dubouloz (1938), Prat (1936), and Lucas (1934).

Ultra-violet transmission data on suspensions of organisms have been reported by Ehrismann and Noethling (1932) for bacteria and yeast, by Noethling and Stubbe (1934) for Antirrhinum pollen, and by Giese and Leighton (1935) for paramoecia. This method is far from satisfactory owing to the scattering by the organisms and the difficulties of secur-

ing data of absolute value.

The present investigation on the absorption characteristics of corn pollen has grown out of a need for accurate information as to the actual energy reaching the chromosomes within a pollen grain in order to interpret genetic results (Stadler and Uber, 1938). No existing data on the composition of pollen, either of walls or contents, are sufficient to solve this problem on the basis of known absorption curves of the chemical constituents.

The writer wishes to record his appreciation of the technical assistance of Mr. Roger Winters and Dr. Ernest W. Landen, and of the privilege of frequent consultation with Professor L. J. Stadler. The quartz microscope was made available by a generous grant of the University of Missouri Research Council.

Theory of absorption measurements with the microscope.—When a parallel beam of radiation is absorbed in a homogeneous layer of substance of uniform thickness, D, the relation between the incident flux,  $I_0$ , and the transmitted flux, I, can be expressed by the equation:  $I = I_0 e^{-kD}$ , where k is the extinction coefficient for the substance and e is the nape-

<sup>1</sup> Received for publication August 11, 1939.

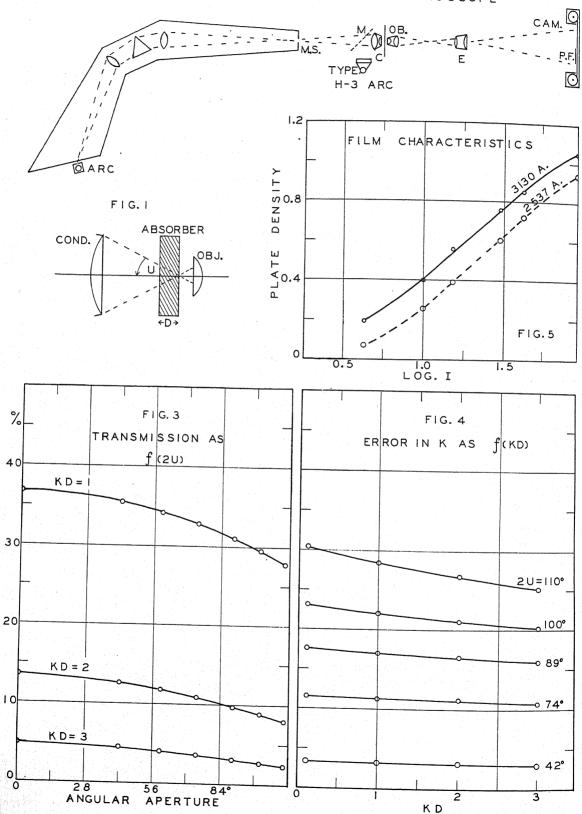

rian logarithm base. Accurate determinations with the microscope of the extinction coefficients, k, for a substance at various wave lengths, will be seen to depend on a knowledge of several factors, which will now be discussed in some detail.

Since energy measurements are made on the image formed by the microscope, it is essential that there be exact correspondence between radiation intensities at the image and at the object. For objects which are large compared to the limit of resolution of the microscope, this condition of correspondence depends only on the degree of optical perfection of the microscope. In other words, the image must be a perfect replica of the object. The most important corrections of the lenses in an ultra-violet microscope are for spherical aberration, coma, and curvature of the field, since chromatic aberrations do not enter where only monochromatic radiation is used. Compensation for the variations in spherical aberration with wave length can be effected by alterations in tube length. Quartz objectives as developed by Köhler (1904) are unusually well corrected for the aberrations in question. A chromatic correction, though highly desirable for spectrophotometric investigations, is practically impossible owing to a lack of suitable optical materials.

Several properties of an object under investigation may influence the determination of absorption data—namely, its size, shape, refractive index, and degree of homogeneity. The case where the object is large compared to the limit of resolution of a microscope has already been mentioned and is the one with which the present study is concerned. Where the dimensions of an object are of the same order of magnitude as the limit of resolution, the intensity ratios in the image no longer correspond to those in the object; indeed the shape of the image may bear little or no resemblance to the shape of the object. Hence, absorption measurements become very difficult or even impossible. This case has been discussed at some length by Caspersson (1936), who has also worked out the consequences of shape for absorption determinations as a function of the refractive index of the object. Caspersson concludes that an object must have dimensions approximately four times the wave length of the radiation used in order for its image to simulate the object well enough for absorption measurements.

Where a convergent beam of radiation is transmitted through an absorbing layer as depicted in figure 1, various parts of the beam traverse different distances of path within the layer. Hence, one cannot employ simply the thickness, D, of the layer in the equation to obtain the extinction coefficient. Instead of the transmitted flux through the absorbing substance and the control, I and  $I_0$ , respectively, being

FIG. 2 MONOCHROMATOR AND QUARTZ MICROSCOPE

related by the equation  $I = I_0 e^{-kD}$ , one finds, as did Caspersson (1936), the following ratio effective:

$$\frac{I}{I_o} = \frac{\int_o^u \sin u \ e^{-kD/\cos u} \ du}{\int_o^u \sin u \ du}$$

where 2u is the angle subtended at the object by the objective or by the condenser, whichever is the smaller. Upon integrating this expression, one obtains the following infinite series:

increased. In practice this need not be the case if there is appreciable scattering by the object, for the greater the aperture the larger the quantity of scattered radiation which will enter the objective. As will be seen from figure 9, the transmission of pollen walls as measured with a 2.5 mm. objective is greater than the value for a 6.0 mm. objective. Some idea of the amount of scattered radiation can be obtained in this manner, but to be quantitative one would

The following infinite series:
$$\frac{I}{I_o} = \frac{\left[ -e^{-kD/\cos u} \cos u - kD \left( \log \sec u - \frac{kD \sec u}{1 \cdot 1!} + \frac{(kD \sec u)^2}{2 \cdot 2!} - \frac{(kD \sec u)^3}{3 \cdot 3!} + \ldots \right) \right]_0^u}{1 - \cos u}$$

This equation can be evaluated either directly or by graphical integration for the various apertures which are ordinarily used in the quartz microscope, assuming definite values for kD. The ratios of  $I/I_0$ for various angular apertures can be compared with the ratio of  $I/I_0$  which would be given for a parallel beam (0 angle) by referring to the curves in figure 3. The curves show the percentage transmission for kD equal to 1, 2, or 3. The percentage error in the extinction coefficient as a function of kD for various angular apertures is shown in figure 4. It will be seen that the error in k when using the 6.0 mm. dry quartz objective with an angular aperture of 42° is less than 4 per cent and that this error in k is fairly constant with respect to kD, decreasing from 3.5 to 3.1 per cent as kD increases from 0.1 to 3.0, which corresponds to a change in transmission from 90 to 4.5 per cent. For the 2.5 mm. glycerine-immersion objective with an angular aperture of 90 degrees, the error in k is around 17 per cent, while the 1.2 N.A. immersion objective (2u = 110°) would result in an uncorrected value of k about 25-30 per cent too high.

Since k is proportional to the cologarithm of the transmission  $I/I_o$ , it is obvious that the variations in transmission of an absorbing layer with aperture must be greater than those just given for k. The transmission as measured with the 1.2 N.A. objective is around 50 per cent of that for a parallel beam when kD = 3, 60 per cent when kD = 2, and 75 per cent when kD = 1. For the 6.0 mm. objective, the corresponding transmissions range from 90 to 96 per cent and for the 2.5 mm. immersion objective, from 71 to 84 per cent, respectively, of the values obtained by using parallel radiation.

According to the above theory, one would anticipate a decrease in transmission as the aperture is

have to know the distribution of scattered radiation as a function of the angle of scattering.

Apparatus and technic.—The ultra-violet microscope.—The arrangement of the quartz microscope with reference to the monochromator and accessory equipment is shown in figure 2. The horizontal disposition proved highly satisfactory, a stable optical bench serving as a base upon which each part of the microscope could be adjusted independently.

The optical equipment consisted of the standard Zeiss quartz condenser, the 5, 7, 10, and  $14 \times$  eyepieces, and the 6.0 mm., 2.5 mm., and 1.7 mm. objectives, the last two objectives being for glycerine immersion. These have been amply described by Köhler (1904). Although corrected for the wave length 2750 Å, the objectives can be used satisfactorily over a range of several hundred ångstroms, particularly where finest detail is not a consideration. Moreover, the slight alterations of the corrections with wave length can be obviated by proper changes in the tube length of the microscope, should it prove important. As an immersion fluid, glycerine-sucrose solutions were employed.

Focusing was accomplished in the visible with the mercury 4358 Å line; then the objective and condenser were displaced to the focus for the desired wave length in the ultra-violet by means of a micrometer screw with a calibrated drum-head reading to microns. Calibration charts were plotted in terms of the displacements necessary to move the objective or condenser from the 4358 Å focus to any of the ultra-violet wave lengths used. It was not essential to make more than one setting for focus except for the immersion objectives, and then only when interested in detailed structure.

Fig. 1-5.—Fig. 1. Cross section showing the variation in the length of the radiation path through an absorbing layer, D, when a convergent beam is employed. Path is given by  $D/\cos u$  for any angle u.—Fig. 2. Cross section of the optical system of the quartz microscope as used for photography. Variation in the measured transmission  $I/I_0$ , as a function of the angular aperture of the convergent cone, for various values of kD. The value for parallel radiation is shown at O angular aperture. —Fig. 4. The percentage error in k as a function of kD, when  $I/I_0$  is measured at the various angular apertures indicated for each curve.—Fig. 5. Characteristic optical densities of the photographic film when plotted against log(I), where I is the percentage transmission of the calibrated platinum filters or of the absorbing sample, respectively.

An 85 watt high pressure mercury arc (General Electric Vapor Lamp Company type H3) proved convenient as an auxiliary source of visible radiation, enabling one to focus on a ground glass. This arc was placed at the side so that its radiation could be reflected into the condenser at will by means of the mirror M shown in figure 2. Corning glass filters were used to isolate the 4358 Å line.

A water-cooled capillary mercury arc operating at atmospheric pressure furnished the ultra-violet radiation, which emerged from a quartz window in the side of the brass water cell. Distilled water was used for cooling. The arc had a power consumption of about 200 watts, the current being 4 amperes. A slit in the water-cooling chamber served as an entrance slit for the Hilger medium quartz spectrograph which was used as a monochromator. In order to keep the microscope in permanent alignment, it was found convenient to reverse the usual optical path through the spectrograph. For this purpose, the plate holder at the camera end of the spectrograph was replaced by a sliding attachment which carried the arc and its water-cooling cell. Desired wave-lengths were obtained by moving the arc along the position normally occupied by the spectrum plate. Mercury lines used were: 3650, 3341, 3130, 3022, 2967, 2894, 2804, 2652, 2537, 2483, and 2378 Å.

Methods of measurement.—Three methods of making absorption measurements have been used, all of which require at least a microscope condenser, and two make use of a complete quartz microscope. The first method consisted of focusing a small spot of radiation about .035 mm. in diameter on the object to be investigated and measuring the incident and transmitted flux by means of a Geiger-Mueller photoelectric counter. The counter-tube had a cylindrical cadmium electrode within a quartz envelope filled with hydrogen or helium. The photoelectric threshold of cadmium is around 3500 Å so that visible light does not interfere. Since the irradiated spot was extremely small, the counter-tube was built to correspond, the cathode being only 6 mm. in diameter. The counting circuit was a scale-of-eight type, similar to the one described by Shepherd and Haxby (1936). The principal disadvantage of the Geiger-Mueller arrangement, apart from experimental difficulties, was the time factor, for each single observation required counting for a minute or more, while a complete absorption determination at a single wave length often demanded up to ten minutes. On the other hand, radiation intensities could be kept low. The final data reported in this paper were not obtained with the counter-method, but preliminary results with the counter were corroborated by the results given here.

In the photographic method of measuring absorption, a roll-film camera was employed on the microscope so that 32 pictures could be taken on each film, thus enabling one to make several exposures at each wave-length investigated, varying either the focus or the exposure time. Placed immediately in front

of the film and covering half of each exposed strip was a calibrated platinum step filter (P.F. in fig. 2). Hence, for every exposure, a graded series of photographic densities for comparison was available. In practice, the densities of these photographic images of the clear field, produced by ultra-violet radiation whose intensity was known in terms of the original incident intensity, were measured with a microphotometer and plotted as ordinates on a graph with the logarithm of the ultra-violet radiation intensities as abscissae. These intensities were given by the percentage transmission of the various platinum filters.

Figure 5 illustrates a typical characteristic curve for the photographic film and shows how the transmission for a pollen wall can be interpolated from it when the density of the wall image is known. In practice, it was customary to photometer the image of the wall first, then to photometer only the two filtered images of the field having densities immediately higher and lower, respectively, and interpolating by means of a straight line. Two or more exposures were usually made for different lengths of time at each wave length and the results averaged.

Investigators familiar with photographic spectrophotometry will realize the great practical advantage in having comparison standards along with every exposure, each exposure being at a single wave length. In this way, one avoids entirely the variations in the characteristic curves of the film which result from their dependence on wave length, emulsion, kind and extent of development.

The merit of the platinum filters or step-weakeners for decreasing the intensity of the direct radiation beam is owing to their practically constant transmission over a wide wave length range. Actually the transmission does increase slightly with decreasing wave length (see Follett, 1936). Calibration measurements for the particular platinum step-weakeners used here are given in table 1.

Table 1. Transmission in percentage of platinum stepweakeners of varying thickness.

Wave-length	1	2	3	4	5
3650 Å	4.54	9.9	14.6	29.9	40.2
3130 Å	4.14	10.0	14.5	30.5	41.5
2804 Å	4.06	10.9	15.8	30.8	41.6
2537 Å	4.23	9.8	15.6	30.8	40.6
2399 Å	6.38	12.3	18.3	34.6	44.0

These step-weakeners have been prepared by cathodic sputtering of platinum on thin slips of crystal quartz about 6 mm.  $\times$  25 mm.  $\times$  0.6 mm. in thickness. Properly protected surfaces will retain their calibration indefinitely.

In using the photoelectric method for absorption measurements, the photographic plate was replaced by a gas-filled caesium-oxide-on-silver photocell. The spectral sensitivity of this photocell has been described by Young and Pierce (1931). The 6 mm.

dry objective was employed in combination with the lowest power condenser (N.A. = 0.35) in order to secure a longer working distance. To increase the radiation intensity at the image, magnification was kept at a minimum with the 5×eyepiece.

The photoelectric current was amplified with a direct current amplifier of the type described by Penick (1935), using the Western Electric tube no. D-96475. The grid-leak resistance was 10<sup>8</sup> ohms. A high sensitivity galvanometer in conjunction with a lamp and scale at 2 meters distance gave ample deflections, the stronger lines such as 2650 Å requiring only 0.01 of the full sensitivity.

The sample being measured was placed on the stage so that it could be rapidly displaced between two fixed stops, one stop permitting a measurement through the sample, the other through a control solution.

Description and preparation of pollen.—Pollen grains of Zea mays are approximately spherical with a mean diameter of 93 microns. The walls are thin and smooth, usually contain one pore surrounded by a thickening in the wall. Under high magnifications, however, the walls exhibit a stippled appearance. The nuclei of mature pollen are three in number, two generative nuclei having a long sperm-like structure (Rhodes, 1934; Weatherwax, 1919) and a vegetative nucleus about  $10~\mu$  in diameter (Weatherwax, 1919).

The moisture content of corn pollen is high, approximating 60 per cent. Of major importance is the reserve food supply which consists primarily of small starch granules. These starch grains are very effective scattering centers for radiation.

Pollen was obtained from freshly opened anthers grown in the greenhouse. For measurements on wall transmission, an individual grain was crushed in distilled water, where the wall was freed from its protoplasmic contents, and then removed to a 50 per cent mixture of glycerine and water on a quartz slide. A coverslip was added, care having been taken to see that a single layer of wall was present. Measurements of  $I_0$  were taken through the glycerinewater layer adjacent to the sample of wall.

Determinations of transmission by the contents of pollen grains were made by crushing out the contents to form a layer 8 microns thick. This layer was free from walls in the region where measurements were taken. Thickness of the layer was controlled by spacers of aluminum foil placed between quartz slides, the latter being held together between brass plates. A vaseline seal prevented evaporation. In this case, too, the control intensity,  $I_0$ , was measured through a 50 per cent glycerine-water layer of the same thickness as the contents.

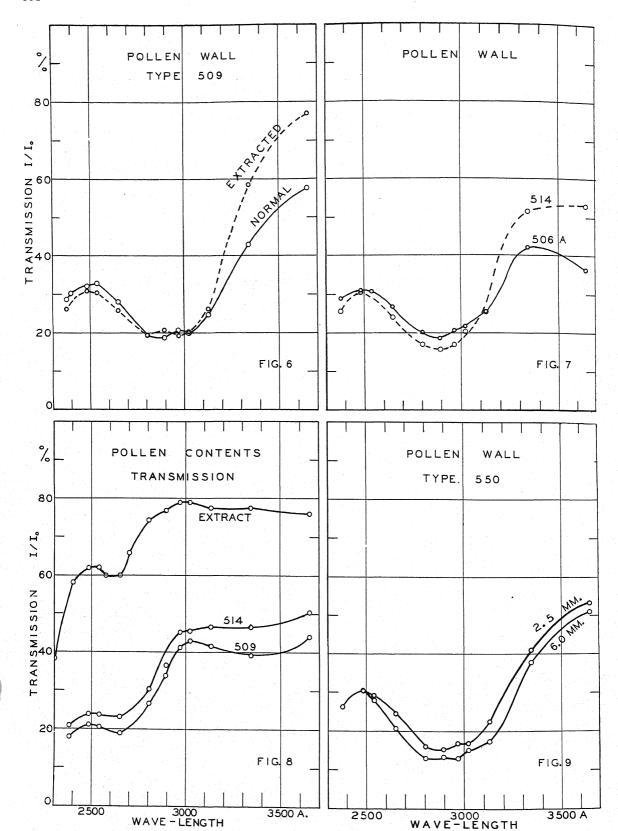

The pollen came from several genetic stocks which had been used extensively in a study of the genetic effects of ultra-violet radiation (Stadler and Sprague, 1936; Stadler and Uber, 1938). Family 509 was a purple variety with the homozygous dominant characters "A B Pl." Family 514 was characterized by the genetic markers "A R j L" and was

of interest because it had given some indication of reacting differently when treated with ultra-violet. Family 550 had the markers "A C r/rs v gl lg j." Family 506A-4 was "Nojoya teosinte," the pollen grains of which were rather variable in size, but always much smaller than corn pollen. The larger grains only have been used. Since the teosinte (Euchlaena mexicana) is a genus related to Zea, it offered the possibility of possessing a different absorption spectrum, either qualitatively or quantitatively. Nothing regarding the chemical composition of these particular varieties of pollen is known.

Experimental results.—Pollen walls.—Transmission curves for a single thickness of wall, with measurements made only at the prominent mercury emission lines, are shown in figures 6 and 7 for various pollen wall samples. In figure 6, family 509 is represented by two curves, one being for normal walls, the other for walls extracted to remove pectin and water-soluble constituents. These two curves do not differ appreciably except at the two longest wave-lengths where observations were made. The curve for the extracted walls is an average of two sets of data obtained from two pollen walls extracted in different ways. Both gave closely similar results. The first method of extraction consisted of treating the walls with a 0.5 per cent aqueous solution of sodium citrate for 30 minutes at 80°C. The second method comprised autoclaving the walls at 120°C. for 30 minutes in 2 per cent HCl, rinsing in distilled water, and then autoclaving again under the same conditions, but with the walls in 2 per cent KOH. Following another rinsing in distilled water, the walls were placed in the usual 50 per cent glycerine-water mixture preceding the transmission measurements. The only apparent result of the extraction was to remove substances possessing absorption bands in the region extending from 3130 Å to longer wave-lengths. This question will be discussed in a later paragraph.

The curve for the normal walls of family 509 represents the average of eight trials, each trial consisting of a complete spectral transmission curve for a single pollen wall. Normal as well as extracted pollen walls from family 509 exhibited a broad region of minimum transmission centering around 2900 Å and extending from 2800 to 3000 Å. This broad minimum was also characteristic of the "Nojoya teosinte" (family 506A) and families 514 and 550, the latter two being represented in the curves of figures 7 and 9, respectively. The teosinte pollen, however, had a minimum transmission at 3650 Å. This would seem to indicate the presence of a water-soluble substance with an absorption band in the vicinity of 3650 Å, possibly a pigment.

All pollen samples measured had similar transmission curves at the shorter wave-lengths, all having a maximum at 2500 Å. Not only the qualitative features of the curves agreed, but also the quantitative data are in substantial agreement. Families 514 and 550 gave somewhat lower minimum values of transmission.

It has already been stated that the transmission values apply to pollen walls immersed in a liquid. For a dry wall in air, there would be an additional reflection loss amounting to around 4 per cent for each air-wall interface. This means that the ultraviolet radiation which could penetrate to the protoplasmic layer in contact with the inner side of the wall of a pollen grain in its natural condition would amount to about 96 per cent of the values given in the accompanying curves of figures 6, 7, and 9.

Pollen contents.—Transmission curves for the heterogeneous contents of corn pollen, measured photoelectrically on 8 micron layers of the crushed grains, but excluding wall material, are reproduced in figure 8. The curve for family 514 is an average of five trials, all on pollen from the same plant. Similarly, the family 509 curve represents the average of six trials, a complete wave-length curve on a single pollen sample constituting a trial. A minimum in the transmission occurs around 2650 Å and a maximum around 2500 Å. It will be noted that the transmission in the long wave-length portion of curve is relatively independent of the wave length. This type of curve has been checked by all three methods of measuring intensities—that is, the photographic, the photoelectric, and the Geiger-Mueller counter method. Also an extract of the pollen in a phosphate buffer solution at pH 6.8 shows the same characteristics, as can be seen from the top curve of figure 8. The minimum at 2650 is somewhat more pronounced here since the transmission is higher and no starch granules are present to scatter radiation.

An apparently significant, though slight, difference in the absolute values of the transmission for the two types of pollen contents has been found. This difference is not a function of wave-length and could be due to variations in starch concentration.

DISCUSSION.—Pollen walls.—That plant cell walls absorb ultra-violet radiation has been known ever since the publication of Köhler's (1904) original photographs with the quartz microscope. It had been suspected years before that such was the case and particularly that the outer walls of plants constituted a protection against the ultra-violet radiation in sunlight. Köhler had used only the wave-length 2750 Å, and Schultz (1910), in an extensive survey of plant tissue, confined his photography to 2800 Å. But these wave-lengths are probably never present in sunlight reaching the earth's surface. It may be significant that the only radiation in sunlight capable of producing genetic alterations in corn pollen (Stadler and Uber, 1938) has now been shown to have minimum transmission through the pollen walls. Investigations by Stadler and Sprague (1936) have already shown that sunlight is probably not responsible for the natural mutation rate in corn.

Schultz's (1910) finding that the epidermis and cuticle of leaves are relatively very opaque to 2800 Å has been recently confirmed by Meyer (1938) who claimed that cutin itself is probably responsible for the ultra-violet absorption. Likewise Frey (1925-1926) ascribed to "cutin" the absorbing rôle for leaf epidermis and stated that the cellulose micelles are transparent to ultra-violet. Neither Meyer nor Frey gave any quantitative data or wave-length information.

Pollen walls are regarded generally as composed of cellulose, cutin, callose, and/or pectic substances. These categories are somewhat indefinite and perhaps not mutually exclusive. According to Möbius (1923) most pollen grains are yellow, the pigment residing in the exine or on the sticky surface in almost all the pollens he examined and only rarely in the interior of the grain. Reeves (1928), in a study of partition-wall formation in the pollen mother cells of Zea mays, found the walls to contain callose but not pectin on the basis of staining reactions. On the other hand, cell walls of meristematic tissue are regarded by Tupper-Carey and Priestley (1923-1924) as made up of a protein in combination with pectin materials, cellulose, and fatty acids. It is evident therefore that the ultraviolet absorption of pollen walls could not be predicted from existing data on their chemical composition. In fact, knowing the absorption curve for pollen walls does not help materially in arriving at wall composition owing to the great dearth of absorption data for the separate chemical constituents. Absorption curves for commercial citrus pectin show a maximum at 2800 Å. This may mean that pectin is not present in the walls of corn pollen, but it is not conclusive. However, such a finding would be in agreement with Reeves (1928). Likewise, the results of extracting pollen walls for pectic substances indicates that pectin is not present. Lignin, too, seems excluded if one compares the pollen curves with those of Herzog and Hillmer (1931) on lignin derivatives, who reported maxima around 2800 Å.

The only other known data on absorption by pollen has been reported by Noethling and Stubbe (1934) for Antirrhinum majus. They used a suspension of pollen grains in 30 per cent ethyl alcohol and obtained a curve very similar to the one given here for the walls only of Zea pollen. Preliminary results on whole Antirrhinum sp. pollen grains by the photomicrographic method do not confirm the curve of Noethling and Stubbe for the pollen suspension. It seems probable that in the suspension method the absorption by the walls predominated, as might be anticipated, since the ellipsoidal Antirrhinum grains swell up to a spherical shape in 30

Pollen wall transmission curves as measured with 2.5 mm. and 6.0 mm. focal length objectives. See text for comment.

per cent alcohol, and the pollen contents tend to contract into a small volume.

Pollen contents.—The low values for the transmission of ultra-violet by thin layers of contents is owing in part to the scattering of radiation by the starch granules. However, the selective absorption, particularly at wave-lengths shorter than 2967 A, is very marked with a minimum occurring in the neighborhood of 2650 Å. Curves indicating absorption in this region are not peculiar to pollen protoplasm but are characteristic of a number of organisms such as bacteria (Gates, 1930), yeast (Landen and Uber, 1939), sea urchin eggs (Vles and Gex, 1934), sporidia of Ustilago zeae (Landen, 1939), and the cytoplasm of Drosophila eggs and onion root tips (Caspersson and Schultz, 1938, 1939, respectively). Caspersson (1936) envisages a nucleic acid metabolism associated with cytoplasmic processes and ascribes the absorption to nucleotides or nucleoproteins. Absorption by starches and sugars is not sufficiently intense in this region to account for the curves obtained even if they did happen to possess selective absorption at the correct wave-lengths.

Chemical analyses of corn pollen have been made by a number of workers. The bulk of the pollen grain consists of water, starches, and sugars. Other substances found by Anderson and Kulp (1922) and Anderson (1923) were inosite, choline, l-proline, nonakosane (C<sub>29</sub>H<sub>60</sub>), phytosterol, and various phosphatides. Adenine gave them a negative test but has since been identified in corn pollen by Vinson (1927) and Miyake (1922, 1924). In addition Vinson reported arginine, lysine, tyrosine, β-hydroxyglutamic acid, a glutelin fraction, and a crystalline pigment believed to be a flavone or a flavonal. The corn protein, zein, is probably present. Its amino acid composition includes in decreasing order of importance the following: glutamic acid, leucine, proline, phenylalanine, tyrosine, alanine, β-hydroxyglutamic acid, valine, aspartic acid, arginine, serine, histidine, and cystine.

Of the various components named, those known to have selective absorption in the ultra-violet region in question are adenine with a maximum at 2600 Å, zein with a maximum at 2750-2800 Å and corresponding presumably to its tyrosine and phenylalanine content, and the flavone pigment with an absorption band probably around 3300-3600 Å. Adenine is associated with nucleic acid and may be present in that form or as a nucleo-protein. It seems probable that the constituents just named, which are known to be present, account for the major part of the absorption. Since numerous substances have absorption bands in the region in question, and since the composition of pollen is so complex, it is obviously impossible to make a specific analysis on the basis of absorption data alone. This is especially true when the necessary absorption curves are not even available for the known pollen constituents in their pure state. Of the substances which may be present in minute amounts, and thus contribute to the totality of the transmission picture, nothing can be said.

Whole grains.—It may occur to some that measurements might have been made to better purpose by using intact pollen. Apart from technical difficulties due to the shape and size of a grain, it will now be seen from the data obtained for thin layers of contents and for the walls that such measurements would be practically impossible. A central section through a whole grain comprises at least eleven of the 8-micron layers which were employed for measurement. Since each layer transmits only 20–50 per cent of the radiation incident upon it, depending on the wave-length, an entire grain could transmit but a very small fraction of 1 per cent.

In addition to the analytical value of absorption data with reference to chemical composition, it has perhaps a more important place in connection with genetic irradiation studies. In the latter connection, computation of the energy actually reaching the nuclei or chromosomes of the pollen depends on a knowledge of the transmission curve for both the wall and the contents. Calculations of this sort for corn pollen are complicated by the fact that the two generative nuclei occupy eccentric positions in the grain so that no simple statement can be made with respect to the transmission of radiant energy to the nuclei. Detailed consideration of this problem will appear in a forthcoming paper by Dr. L. J. Stadler and the present writer.

### SUMMARY

Theoretical considerations involved in the measurement of absorption spectra with the microscope are discussed.

Photoelectric, Geiger-Mueller counter, and photographic methods of ultra-violet spectrophotometry with the microscope are described, the photographic method employing step-weakeners of platinum on quartz as a basis for density determinations.

Walls of Zea mays pollen grains of varying genetic constitution have similar transmission curves, characteristic features being a broad minimum centering around 2900 Å, a maximum at 2500 Å, and some variation among pollen varieties in the region 3200-3600 Å. A single wall transmits 15-20 per cent at 2900 Å.

Contents of pollen grains are characterized by a minimum in transmission around 2600 Å, a maximum at 2500 Å, and a fairly low but rather constant transmission from 3000 Å to 3600 Å. An 8 micron layer of pollen contents transmits 19–23 per cent at 2650 Å.

Only a limited correlation of corn pollen absorption spectra with chemical constitution is possible at present owing to a lack of adequate chemical analyses and essential absorption data for the individual components present.

# FACTORS INFLUENCING THE EFFICIENCY OF PHOTOSYNTHESIS <sup>1</sup>

# Robert Emerson and Charlton M. Lewis

Warburg and Negelein (1923) reported that Chlorella, when grown under suitable culture conditions, could assimilate carbon dioxide at the rate of 0.25 molecule per absorbed quantum of visible light, a yield close to the supposed theoretical limit. Before this quantum yield becomes an acceptable basis for theoretical discussions of the assimilatory mechanism, three questions require consideration. First, is the value reproducible in other laboratories? Second, can still higher values be obtained? And third, do the measured values truly represent the quantum yield of the assimilatory mechanism?

Although Manning, Stauffer, Duggar and Daniels (1938), using methods different from Warburg and Negelein's, found considerably lower yields, the first question has been answered in the affirmative by Rieke (1939), who obtained yields close to 0.25 by following the technique of Warburg and Negelein in detail. The second and third questions are dealt with in the present paper. Part I shows that the efficiency of photosynthesis is critically dependent on a number of factors, and that favorable combinations of these factors lead to quantum yields as high as 0.33. Part II presents experimental evidence that two assumptions upon which ordinary manometric measurements of photosynthesis depend do not hold for the conditions of the quantum yield measurements, so that the published values should be regarded as characteristic of the method by which they are obtained, rather than of the assimilatory mechanism

Our experimental technique and method of calculation of results are explained in Part III. The general procedure was the same as that of Warburg and Negelein. Liquid cultures of Chlorella were grown to a suitable density, harvested, washed, and subjected to manometric measurements of photosynthesis in sodium light ( $\lambda = 589 \text{ m}\mu$ ) of known energy content. The pressure change due to photo-

<sup>1</sup> Received for publication September 14, 1939.

synthesis was computed from observations made during alternating ten-minute periods of light and darkness, and from this pressure change the photosynthesis was computed, exactly in the manner of Warburg and Negelein. As will be shown in Part II, the values obtained in this way are probably not true efficiencies but may be anticipated to be proportional to the true values. In Part I, where we discuss the influence of various factors on efficiency, we mean only the efficiency measured by this particular system of computation.

PART I. CONDITIONS LEADING TO HIGH EFFICIENCY. -Composition of the culture medium.—The addition to the medium of small amounts of certain substances may profoundly affect the efficiency of cells grown in the medium. Traces of organic materials (yeast extract, adenine, uric acid) sometimes increased growth but failed to improve the quantum yield. Traces of inorganic materials (particularly various heavy metals) caused increases in efficiency as well as in growth. Little attention has heretofore been paid to heavy metals in connection with the quantum yield of photosynthesis, probably because the necessary traces have usually been included in the salts and water used to prepare the medium. But failure to obtain high efficiency may be due to the use of salts and water which contain too little of the essential heavy metals. If very pure water is used, it becomes necessary to supplement the ordinary formula for the culture medium. We have found that the addition of an extra amount of ferric sulfate may greatly increase the efficiency of cells grown in a given medium. It has been possible to show that this improvement is not due to the iron itself, but to impurities contained in abundance in this particular iron salt. Indications of the identity of the impurities responsible have been obtained by direct addition of traces of eleven different elements to the culture medium.

Table 1. Comparison of efficiency and growth with two iron concentrations and with water from various sources. Efficiencies in all tables are averages of results from two successive light exposures. Except in table 3, the age given includes three days at reduced intensity.

We shall take up first the importance of the source of the water and the amount of iron added to the medium. Then evidence will be presented to show that the effect of both the iron and the waters is due to traces of elements other than iron. Following this, experiments with the direct addition of traces of various elements will be described.

The influence of the water and the amount of iron salt used to prepare the culture medium.—Table 1 shows the efficiency of photosynthesis (quantum vield) for cells grown in water from seven different sources. The table is divided into two parts, the lefthand part showing the results when the ferric sulfate concentration was  $0.5 \times 10^{-5}$  molar, the righthand part for  $2.5 \times 10^{-5}$  molar. The major nutrient salts were the same in each case. Details of preparation of the medium are to be found in Part III. Both parts of the table show considerable dependence of the yield on the water used, and in every instance except the Searsville Lake water, the yield was appreciably greater with the higher concentration of iron. However, the improvement obtained with the extra iron tends to be smaller in those cases where the lower concentration of iron gave a fairly high vield. The highest yields with the low iron concentration were in Baltimore tap water and commercial distilled water. The increase in yield with five times as much iron was 18 per cent and 15 per cent, respectively. The glass distilled water medium, which might be expected to be most deficient in traces of heavy metals, gave the lowest yield with the low iron concentration and showed an increase of 95 per cent with the fivefold iron concentration. The failure of the yields in Searsville Lake and laboratory distilled water to respond so markedly to the higher iron concentration may have been due to the presence of toxic substances in these waters.

The growth as well as the efficiency depends on the water and the amount of iron added to the medium. Consistent correlation between growth (culture density) and efficiency is lacking, although the higher iron concentration gave greater growth as well as higher efficiency in every case but one.

For comparison with Rieke's yields, and with Warburg and Negelein's, we should look first at our results with the lower concentration of iron, because they specified the same iron concentration for their media (1  $\times$  10<sup>-5</sup> molar ferrous sulfate). In other respects their media were comparable with ours, though not identical. They used twice the concentration of the major nutrient salts in our medium. Since we found no improvement in efficiency with the double concentration of nutrient salts, we regard the iron and the water as the decisive factors. With the low iron concentration only two of our waters gave yields comparable with theirs-Baltimore tap water and commercial distilled water. With the fivefold iron concentration, on the other hand, most of the waters gave yields as good as theirs or better. From our results with the low iron concentration, we must conclude that they were fortunate in their choice of waters. Warburg and Negelein used Berlin tap water, and Rieke used water distilled from a tin still.

Some of the waters listed in table 1 call for explanation. The laboratory distilled water was made by distillation of the laboratory tap water in a tinned still. To make the glass distilled water, the laboratory distilled water was redistilled from an all-Pyrex still. The residue from this still after a number of distillations was the water referred to as still residue. The Baltimore tap water was included because we first thought Rieke had used this in the preparation of his medium. The Searsville Lake water was locally impounded surface water.

In table 1, as well as in subsequent tables, there is a column showing the estimated percentage of the incident light which was absorbed by each cell suspension. This percentage of the measured light entering the vessel was used in computing the efficiencies. The visual method which was used for estimating the absorption, and the resulting uncertainty in the efficiency are discussed in Part III. In the few cases of absorption below 80 per cent the error may be as much as 10 per cent, but for absorption between 95 and 100 per cent, as in most of the measurements, only a negligible uncertainty is introduced.

The elimination of iron as a factor responsible for high efficiency.—It might be supposed that the generally lower yields with the low iron concentration were due to iron deficiency and that in those cases where the yield compares favorably with that in the fivefold iron concentration, the water had supplied the necessary extra iron. But one would hardly expect this to be the case for the commercial distilled water, and figures furnished by the Baltimore City Water Department show that the iron present in Baltimore tap water is only about one twentieth of our low iron concentration. Warburg and Negelein's analysis of their Berlin tap water showed that it contributed only one tenth of the total iron in their culture medium. The dependence of the efficiency on the source of the water must therefore be chiefly attributed to the presence of constituents other than iron. This suggests that the superiority of the fivefold iron concentration is due to traces of impurities added with the iron, rather than to the additional iron itself.

Support for this conclusion is derived from observations of the dependence of growth and efficiency on the age of the culture. The curves in figure 1 show growth and efficiency plotted against age of culture in days, for the low iron concentration (broken curves) and for the fivefold iron concentration (solid curves). In both cases the media were prepared with glass distilled water. If the iron concentration is high, the quantum yield remains essentially constant at a high value throughout the 12 days of the experiment. Growth, though starting slowly, shows an early increase and continues at a uniformly high rate for the same period of time. In the lower iron concentration the young cultures show

an efficiency nearly as great as with the fivefold iron, and a superior initial growth rate. But both the rate of growth and the efficiency drop rapidly after the first few days, as if some essential constituent in the culture medium were becoming exhausted. It seems unlikely that this decline both in growth and efficiency could be due to lack of sufficient iron, because the same medium prepared in a suitable water, which

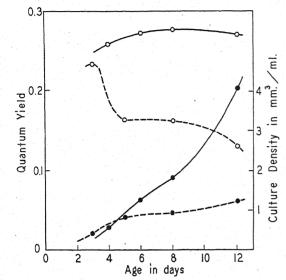

Fig. 1. The dependence of growth (solid circles) and efficiency (open circles) on age of culture. The broken curves are for the low iron concentration (.5  $\times$  10<sup>-5</sup> molar ferric sulfate), and the unbroken curves are for the five-fold iron concentration (2.5  $\times$  10<sup>-5</sup> molar ferric sulfate). Cultures were grown at 900 lux, with no reduction in light intensity. For the measurements at three and four days, several cultures were pooled, in order to obtain sufficient quantities of cells.

as we have seen need not contribute an appreciable amount of iron, will maintain excellent growth and high efficiency to an advanced age. The persistent high growth rate and quantum yield with the five-fold iron concentration must therefore be due to elements other than iron which are carried as impurities in the ferric sulfate. The deficiency which manifests itself early in the development of the culture with the low concentration of iron can be largely made up by the addition of five times as much ferric sulfate, because of the impurities contained in the ferric sulfate.

If the beneficial effect of larger amounts of iron is due to impurities, then for a given amount of iron, the efficiency should depend upon the purity of the iron source. Table 2a shows the efficiency for four cultures, grown in glass distilled water media, each of which received the same amount of iron, but from four different sources. In general, both growth and efficiency were better, the lower the purity of the iron. The ferrous tartrate, furnished by the plant nutrition laboratory of the University of California at Berkeley, had been specially purified to free it from traces of heavy metals. This gave the lowest efficiency and poorest growth. The fact that the reagent ferric sulfate, presumably of higher purity than the c.p. grade, gave the highest growth and efficiency may be an indication that toxic as well as beneficial impurities are involved; but it must also be remembered that the standards of purity of chemical reagents may bear no consistent relation to the minute traces of elements important in plant nutrition (Arnon and Stout, 1939, p. 145).

The direct addition of microelements.—The low efficiency characteristic of the low iron concentration in glass distilled water can be increased not only by the addition of more iron or the use of a more

'Table 2. a, Dependence of efficiency upon source of iron. b, c, Effect on efficiency of addition of microelements to medium with low and with high iron concentration. All media were made up in glass distilled water, Quantities of supplementary solutions are per liter of medium.

favorable water, but also by the direct addition of certain elements to the medium. The elements chosen were those found by Hoagland and his collaborators to be important in the culture of higher plants and designated by them as microelements (cf. Hoagland, 1937; Arnon, 1938). They very kindly furnished us with two stock solutions containing elements grouped according to their importance. Supplementary solution A5 includes those elements now known to be essential for normal development of certain higher plants (boron, manganese, zinc, copper and molybdenum), while B6 contains elements not yet known to be essential, but known to be definitely beneficial when used as a group (titanium, vanadium, tungsten, chromium, cobalt and nickel). The concentrations of the several elements in the supplementary solutions are the same as specified by Arnon (1938) for solutions A4 and B7. The change of designation to A5 and B6 is due to the recent transfer of molybdenum from the B to the A group. To each liter of medium, Arnon recommends the addition of 1 ml. of each of the supplementary solutions, giving concentrations in the medium ranging from 0.5 parts per million for boron down to 0.01 ppm. for the elements in the B6 solution.

Table 2b shows the effect of adding these quantities of A5 and B6 solution to the medium prepared in glass distilled water with low iron concentration. A5 improves the efficiency 85 per cent, and B6, 29 per cent. Used in combination they increase the quantum yield more than 100 per cent, so that it becomes comparable with the highest yields shown in table 1 for the fivefold iron concentration. It seems not unlikely that the A5 and B6 solutions include some of the same elements responsible for the improvement in yield brought about by the use of favorable waters, or of extra amounts of iron.

Table 2b also shows that the very low yield with iron as ferrous tartrate can be increased 100 per cent by addition of A5 and B6 solutions. The level attained is not so high as when the iron is added as ferric sulfate, probably because the latter contains elements lacking both in the tartrate and in the A5

and B6 solutions, or because the impurities in the ferric sulfate together with the A5 and B6 solutions give a more favorable combination of microelements than the A5 and B6 solutions alone. The possibility also remains that the iron as tartrate is not equal to sulfate in physiological value.

Even the yield obtained by using the fivefold iron concentration can be increased by the addition of microelements. Table 2c shows the effect of three different concentrations of the A5 solution added to the medium in glass distilled water with high iron concentration. The amounts of A5 added were 0.2, 1, and 5 ml. per liter of medium. In each case 1 ml. of B6 was used per liter, as before. The lowest concentration of A5 gave the best results, with an increase of 18 per cent in growth and 17 per cent in efficiency. The two higher concentrations gave only small increases in efficiency over the control (5 and 7 per cent) and inhibited growth. The inhibition of growth, scarcely evident with the middle concentration, was so extreme with the highest concentration that the culture grew hardly at all for the first 10 days. After this it began to grow faster and had reached a good density in 20 days. It is interesting to note that the quantum yield was high in spite of the delayed growth. The inhibition of growth with high concentrations of A5 solution is reminiscent of the slower initial growth characteristic of the cultures with high iron concentration, shown in figure 1. Although this might have been caused by an excess of iron, the growth inhibition due to the A5 solution suggests that it was caused by an excess of some microelement carried by the ferric sulfate as an impurity.

The critical dependence of the growth, and, to a lesser extent, of the photosynthetic efficiency on the amount of A5 solution added to the medium is an indication that certain of the constituents may be somewhat toxic even in the lowest concentration used. Independent variation of the concentration of the individual microelements may be expected to lead to still higher quantum yields.

Table 3. Dependence of efficiency upon light intensity during culturing and during measurement. All cultures were grown in medium with ferric sulfate 2.5 × 10-5 molar in glass distilled water. 0.2 ml. A5 and 1.0 ml. B6 micronutrient solutions were added to all but the first culture, which received equivalent quantities of only manganese, copper, and zinc.

CONDITIONS DURING GROWTH OF CULTURES .--Light intensity .- Table 3 shows that the culturing of cells at high light intensities (6700 lux) is unfavorable for development of high photosynthetic efficiency, although growth is much faster. The existence of an optimum in the neighborhood of 900 lux is indicated. Reduction in light intensity a few days before harvesting, a procedure recommended by Warburg and Negelein, results in a decided increase in efficiency. If the initial period of growth takes place at 900 lux, the table shows that the maximum effect of a 50 per cent reduction occurs after about three days. The preceding period of growth at the higher intensity is important, because if the entire growth takes place at the lower intensity, the efficiency is no better than after growth at 900 lux without reduction. Other combinations of intensities failed to give promise of higher efficiencies. The practice we generally followed, growing the cultures to a moderate density at 20 cm. from a 100-watt bulb and then moving them to 30 cm. for three more days, was the same as specified by Rieke.

Age of the culture and the interdependence of various factors.—As a culture grows older, there is a gradual automatic reduction in the average light intensity within it, due to absorption by the cells. Some tendency of the efficiency to increase with age may therefore be anticipated independently of reduction in the incident intensity (cf. fig. 1). The reverse tendency for the efficiency to decline as essential constituents of the medium become exhausted has already been discussed. The age at which this decline appears may be expected to depend on the light intensity used for growing the cultures, because the faster growth at higher light intensities will result in earlier exhaustion of the least abundant elements. Such an effect has been observed in some of the experiments where cultures were grown at very high light intensities.

Wave length.—Without adequate control of medium, light intensity, and age of the cultures, the dependence of efficiency upon the wave length distribution of the light used for culturing the cells cannot be satisfactorily investigated. Before the interaction of these factors was appreciated, a number of cultures were grown in the blue and yellow mercury lines ( $\lambda = 436$  and 478 m $\mu$ ) and in various regions of the neon spectrum. The results indicated considerable dependence of the quantum yield on the wave

length of light in which the cells were grown. We believe it possible that with proper attention to other factors, control of the wave length may lead to further improvement in the quantum yield.

Temperature.—The temperature at which the cells are grown appears to play relatively little part in the efficiency of photosynthesis. Cultures grown at 10° showed 7 per cent lower efficiency than cultures of corresponding density grown at 20°. No measurements were made with cultures grown at temperatures appreciably higher than 20°. Most of the cultures were grown between 17 and 22°. In any one series the temperature was maintained constant within about 2°.

Conclusions from experiments on culture conditions.—In seeking to identify the culture conditions which determine the efficiency of the photosynthetic apparatus, we have accumulated evidence that optimal adjustment of any one factor depends somewhat on other factors. We have tried as far as possible to combine the factors in such a way as to obtain the highest possible efficiency, but it has been necessary to make arbitrary choices in regard to certain factors, in order to study the influence of others. Further attention to the interdependence of the various factors may be expected to lead to higher values for the photosynthetic efficiency.

CONDITIONS OF MEASUREMENT OF PHOTOSYNTHEsis.—Temperature.—Turning now from the medium and culture conditions to the conditions during measurement of photosynthesis, we have again found a fairly critical dependence of efficiency on a number of factors. The highest efficiencies have been obtained at a temperature of about 10°. Table 4 shows how the yield falls off at temperatures both above and below 10°. Warburg and Negelein, and Rieke, carried out their measurements at 10°, while Manning et al. worked at  $25\,^{\circ}$  for the most part, and made a few experiments at  $1\,^{\circ}$ . From the figures in table 4 one might expect the efficiency at these temperatures to be less than half that at 10°. Wassink, Vermeulen, Reman, and Katz (1938) report quantum yields for Chlorella running from 0.11 to 0.20 at temperatures from 10° to 29°. It appears from their curves that the highest yields were at the higher temperatures, instead of at 10° as in our experiments. However, their purpose was to compare fluorescence and photosynthesis, and the quantum yields were only incidental. Their conditions of measurement were not

Table 4. Dependence of efficiency on temperature during measurement. All cultures were grown in medium with ferric sulfate 2.5 × 10<sup>-5</sup> molar in laboratory distilled water. The lower yield at 10° for A than for C and D is due to the higher intensity used for measurement. Except for culture D, successive measurements were made with increasing temperature.

	Light intensity		uantum y	yield in	molecu	!	Absorp-		Age of		
~ -	0°	5°	8°	10°	12°	15°	20°	tion density per cent mm.3/ml.	culture days

$^{\mathrm{C}}$	380			.210	.253	.226			98.	1.46	10
$\mathbf{D}$	380				.223	.226			98.	1.51	10

comparable with ours in several important respects. Particularly their light intensity was relatively high, so that it was sometimes less a limiting factor than the temperature. This may explain why they obtained lower yields at 10° than at the higher temperatures, but it does not explain why they were able to get such high efficiencies at the higher temperatures. We should bear in mind the possibility that our own apparent maximum at 10° may be in part connected with our technique of measurement.

Light intensity.—In measuring the efficiency of photosynthesis, the light intensity should be so low that it is the only limiting factor. Proportionality of rate of photosynthesis to light intensity is ordinarily used as a test of fulfillment of this condition. We have made most of our measurements at an intensity of about 350 ergs/cm.<sup>2</sup>/sec. (roughly 300 lux). Intensities lower than this did not give appreciably higher yields. In this intensity range photosynthesis is a nearly linear function of intensity within wide limits. The rate for cells grown in bright light is practically linear over a range of 16 fold, but the efficiency is low. The most efficient cells, which are grown at low intensity, show linearity over a range of two- to four-fold. Greater dependence on intensity would be expected with thin suspensions, where all cells are exposed to the full intensity of the incident beam. In the thick suspensions used for efficiency measurements, most of the cells receive light of much lower intensity than the incident beam. Therefore if the incident intensity is raised to the level where other factors become limiting, the deviation from linearity will be less marked than with a thin suspension. Evidence of deviations from linearity may also be obscured by the use of ten-minute periods of light and darkness. The effect of these short periods is discussed in Part II.

Intermittency of the light.—The sodium lamp used for measuring photosynthesis was ordinarily operated on alternating current and showed a distinct intermittency (flicker). This might be expected to influence the photosynthetic yield at high intensities but should not at low intensities if the yield was, as we supposed, independent of the Blackman reaction. We made some experiments with the lamp operated on direct current, without flicker, and found the yields at 10° were the same as with alternating current. Therefore at this temperature our results are fully comparable with other measurements made in continuous light, in spite of the intermittency of the sodium lamp. But at 0° the alternating current sometimes gave a few per cent higher efficiency, suggesting that at this temperature the Blackman reaction may enter as a limiting factor even at very low light intensity.

Carbon dioxide.—Emerson and Green (1938) showed that the rate of photosynthesis at light saturation was strictly independent of carbon dioxide concentrations from 5 per cent down to 0.01 per cent. On general grounds one would expect less rather than more dependence on carbon dioxide at the very low light intensities used for measuring effi-

ciency. Contrary to expectation, we found that the efficiency was quite dependent on carbon dioxide concentration. It was 25 per cent lower at 0.5 per cent than at 5 per cent. Measurements at 12 per cent seemed to be a little lower than at 5 per cent, suggesting the existence of an optimum in the neighborhood of 5 per cent. We made tests to show to what extent our measurements were comparable with those of Emerson and Green and found that the dependence of efficiency on carbon dioxide concentration was a result of certain of the conditions chosen for measurement of efficiency. Emerson and Green made their measurements at 25° with thin cell suspensions and continuous illumination at high light intensity. Our efficiency measurements were made at 10° with thick suspensions and 10-minute exposures to light of very low intensity. We found that with the customary 10-minute light and dark periods, higher light intensities diminished the dependence of the vield on carbon dioxide, in both thick and thin suspensions. The highest intensity used was 5300 ergs/cm.<sup>2</sup>/sec., 15 times the usual intensity for efficiency measurements, but still far below saturation. With this light intensity, the substitution of long light exposures for the 10-minute periods gave the expected independence of carbon dioxide concentration. With both thick and thin suspensions, the rate of photosynthesis was constant from 0.5 per cent down to 0.07 per cent carbon dioxide, a limiting value in good agreement with unpublished results of Emerson and Green at 10°. This agreement, together with the uniformity of our results regardless of suspension density, shows that the dependence of efficiency on carbon dioxide concentration is not due to inadequate mixing of the suspension. The tests show that it is attributable partly to the low light intensity, and partly to the 10-minute light periods used for measuring efficiency.

Conclusions from Part I.—The second question raised in the introduction, whether quantum yields higher than 0.25 are obtainable, has been answered in the affirmative. By identifying and controlling some of the variables upon which the efficiency depends, it has been possible to obtain yields of 0.33, an increase of 25 per cent. There is a distinct probability that still higher yields could be obtained by further adjustment of conditions. The highest values listed are therefore not to be regarded as the maximum possible yield.

The observed dependence of the efficiency on the conditions of measurement has been somewhat unexpected in several instances, particularly the dependence on temperature and carbon dioxide. Mention has been made of the possibility that the peculiar dependence on some of these factors may result from the technique of measurement. The importance of the technique is discussed in the next section.

PART II. SIGNIFICANCE OF THE QUANTUM YIELDS DERIVED FROM MANOMETRIC MEASUREMENTS.—Theoretical considerations.—Because the quantum yield of 0.25, or four quanta per molecule of carbon diooxide reduced, has been regarded as close to the

theoretical maximum, values higher than this acquire a special interest. Warburg and Negelein believed, as a result of measurements of the ratio of exchange of carbon dioxide and oxygen, that carbon dioxide and water were assimilated directly to carbohydrate, without the accumulation of less reduced intermediate products. The conversion of carbon dioxide and water to carbohydrate, being an endothermic process, requires an amount of energy equal to the heat of combustion of the reverse process. In addition, a margin of energy must be available for thermal steps in the synthesis. It is generally agreed that if all the energy is to be supplied as red light (the long wave length limit of green plant photosynthesis) a minimum of four light quanta must be absorbed per molecule of carbon dioxide in order to meet the energy requirements. Although the energy per quantum is greater for wave lengths shorter than red, Warburg and Negelein found the same efficiency in the yellow mercury line ( $\lambda = 578 \text{ m}\mu$ ) as in red. This is a strong indication of the quantum nature of the photochemical part of the assimilatory process. It is not believed that the energy of a single quantum could be divided between two elementary processes, so if four quanta are the minimum number in red, then less than four cannot be expected to suffice in shorter wave lengths (cf. Warburg and Negelein, 1923, p. 210-212). The close agreement between their measured quantum yields and the theoretical maximum of 0.25 has been regarded as supporting the theory of direct synthesis of carbohydrate from carbon dioxide and water. Various mechanisms have been proposed, in which carbohydrate is synthesized from carbonic acid. Yields appreciably higher than 0.25 would be incompatible with such mechanisms, and, partly for this reason, higher yields have not been anticipated. Our measurements, made in sodium light ( $\lambda = 589 \text{ m}\mu$ ), lead to values definitely higher than the theoretical maximum for complete carbohydrate synthesis from carbonic acid. A yield of 0.33 indicates the absorption of only three quanta per molecule of carbon dioxide. Since values higher than the theoretical maximum are obtainable, we must recognize two possibilities. Either the method of measurement leads to incorrect values, or the chemical mechanism from which the theoretical maximum was deduced is incorrect. First we shall present evidence concerning the reliability of the measurements, and then consider possible modifications of the chemical mechanism which would explain the occurrence of yields higher than

The reliability of the manometric measurements.—The pressure changes caused by photosynthesis cannot be measured directly but are deduced from pressure changes measured in both light and darkness, since correction must be made for the respiration that takes place during the light. It is ordinarily assumed that the rate of respiration during the light exposure is equal to the rate measured in the dark before or after the light exposure. However, it is believed that either the light itself or the process of

photosynthesis may accelerate respiration (cf. Gessner, 1938). In this case the photosynthesis computed by correcting the pressure change during a light exposure with the pressure change during an equal period of darkness will be lower than the photosynthesis actually taking place during the light exposure. Such an error may become serious in measurements of efficiency made over very long periods of light and darkness (Manning, Stauffer, Duggar, and Daniels, 1938).

When measurements are made with low incident light and dense suspensions of cells, the total photosynthesis in the suspension may be less than the total respiration, so that photosynthesis is measured as a decrease in respiration. A small percentage change in the respiration during the light will then cause a large percentage error in the estimated photosynthesis. The assumption that the rate of respiration during a light exposure is equal to the observed rate before or after the light exposure becomes of particular importance. Warburg and Negelein sought to minimize the possibility of error from this source by using short periods of light and darkness, so that the respiration would soon reach a steady rate from which it would not deviate greatly in either light or darkness. They found that periods as short as ten minutes gave readily measurable pressure changes and left sufficient time for readjustment in rate of pressure change following changes from light to dark and vice versa. Nevertheless, they believed that respiration during the light exposures was probably somewhat higher than the measured rate during the dark periods.

We thought it possible that still shorter periods of light and darkness might lead to a closer estimate of the rate of respiration prevailing during the light periods, so we made certain improvements in the apparatus to permit the making of readings at shorter intervals. A cathetometer reading in hundredths of a millimeter instead of tenths made the pressure changes over intervals of a minute or less accurately measurable; and the mixing of the cell suspension was so improved that equilibrium in rate of gas exchange between suspension and gas phase was reestablished within one or two minutes after the light was turned on or off. The readings were made without interrupting the shaking of the manometer and vessels, at intervals of one minute, or sometimes 30 seconds.

The use of shorter periods of light and darkness to reduce errors in the respiration measurement did not prove satisfactory. With our improved technique we found that after a change from light to dark, or vice versa, the rate of pressure change was subject to large deviations before coming to the new steady value. An example of the observed deviations is shown in figure 2, where the rate of pressure change is plotted against the time. To make the deviations clear, the measurements selected for figure 2 were made at a light intensity four times that generally used for efficiency measurements. This gave positive photosynthesis, above the compensation point. At

mot .

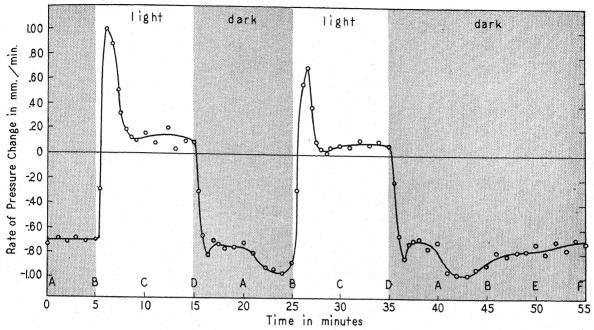

Fig. 2. Deviations from steady rate of pressure change in successive periods of light and darkness. The shaded areas represent the dark periods. Light intensity 1400 ergs/cm.2/sec. The letters A, B, C, etc., designate the times of pressure reading referred to in the text, from which the pressure change due to photosynthesis was computed in various ways.

lower intensity the deviations are much less marked; but we shall show later (table 5) that they still play a significant part in determining the pressure changes from which photosynthesis is computed.

When the light is turned on, a sharp increase of pressure occurs at once and lasts from two to five minutes. Under some circumstances the maximum rate attained may be two or three times the steady rate in the light (the respiration correction being included in each case). It may be noted that, since the mixing in the vessel is not infinitely rapid, the variations in rate of gas exchange at the cells must be even more abrupt than the variations in pressure change recorded by the manometer. When the light is turned off, the rate of pressure change returns approximately to its former (negative) value for a few minutes but then shows an increase. The maximum is reached in about seven minutes and may be 20 per cent above the steady rate, which is regained after 10 to 20 minutes.

These deviations are not due to heat effects, since they disappear when the cells are killed by boiling. Both deviations are affected, though sometimes differently, by the following factors: the conditions of growth of the cells used, the density of the suspension, the light intensity, the partial pressure of carbon dioxide, and the length of time the cells have been in the dark previous to the light exposure. Their dependence on these factors is a strong indication of the physiological origin of the deviations. Values for the efficiency calculated from the observations in figure 2 vary from 0.16 up to the extraordinarily high value of 0.39, depending on whether

photosynthesis is computed from the steady rates, not including any deviations, or from the rates represented by the maximum deviations in both light and darkness. It is not to be supposed, however, that the deviations from steady rate shown in figure 2 are due entirely to irregularities in the rate of photosynthesis or respiration. In part at least, they must be due to changes in the ratio of exchange of oxygen and carbon dioxide.<sup>2</sup> This implies that for the short periods of darkness and illumination used for efficiency measurements the assumptions on which photosynthesis is computed from pressure changes become incorrect.

The computation of gas exchange from pressure measurements with a medium such as ours, in which both oxygen and carbon dioxide are freely exchanged, depends upon a knowledge of the ratio of exchange of these gases. In experiments on photosynthesis, it has generally been assumed that the ratio CO<sub>2</sub>/O<sub>2</sub>, designated by γ, is close to unity. Warburg and Negelein checked this assumption carefully for Chlorella and obtained for the ratio the value -0.9, which they used in calculating their vessel constants. The sign of  $\gamma$  is negative because gas evolution is regarded as positive and gas consumption negative. In order to obtain a sufficient exchange of oxygen and carbon dioxide to permit accurate gas analysis, these measurements were made over periods of one and a half hours or longer, and at high light intensities. The ratio obtained under

<sup>2</sup> Recent experiments have shown that the sudden increase in pressure following the turning on of the light, represented by the peaks between B and C in figure 2, is due principally to evolution of carbon dioxide.

these conditions may not be applicable to the conditions under which high efficiencies have been obtained. The deviations described above indicate that it is not and that the assumption of constant  $\gamma$  is not valid for low light intensity and ten-minute periods of illumination.

The literature already contains a number of observations which indicate that y may vary over a wide range. For example, Gaffron (1939) reports that in media to which sugar has been added algae may under some circumstances accumulate intermediate products of respiration which are probably responsible for deviations in y accompanying the onset of photosynthesis. Recent observations by Blinks and Skow (1938) on the changes in electrical potential of plant cells following changes from light to darkness and vice versa show irregularities similar in some respects to the deviations in pressure change illustrated in figure 2. They have presented evidence that the electrical changes are related to photosynthesis, and among various possible interpretations, they have advanced the suggestion that carbon dioxide may be evolved during the first moments of illumination. They have definite evidence that a sudden burst of oxygen evolution follows immediately upon turning on the light. It must be borne in mind, of course, that such peculiarities in gas exchange may have only an indirect connection with photosynthesis.

Both the uncertainty as to the rate of respiration during the light exposure and the possibility that y may vary over short periods of time furnish grounds for questioning the reliability of efficiency measurements based on manometric determinations of photosynthesis. These two sources of error are in a sense interdependent, since shortening the light and dark periods in order to improve the respiration correction adds to the risk of errors from deviations in  $\gamma$ . The ten-minute periods used by Warburg and Negelein may be regarded as a compromise between these two difficulties. Whether or not it is a good compromise cannot be decided without further knowledge of the behavior of  $\gamma$  under the conditions of their experiments. Our apparently arbitrary decision to follow their schedule of ten-minute periods of light and darkness was reached as a result of observations such as those shown in figure 2.

With a given schedule of timing, the pressure change due to photosynthesis may be computed in several different ways, all of which should lead to the same value were it not for deviations such as those shown in figure 2. It is interesting to note that the method of computation used by Warburg and Negelein was such as to take maximum advantage of the deviations from steady rate. They read the pressure at the times designated A and B in figure 2. Respiration was measured as the change in pressure over the five-minute period from A to B. The fiveminute period from D to A was to permit the carbon dioxide and oxygen exchanged inside the cells during the light exposure to reach equilibrium with the suspending fluid and the gas space. The average of

two successive five-minute periods (A to B) was multiplied by three to give the pressure change due to respiration during the intervening 15-minute period from B to A, which included ten minutes of illumination from B to D. The difference between the observed pressure change for the 15 minutes from B to A and the computed pressure change due to 15 minutes' respiration was assumed to be the pressure change due to photosynthesis during the ten-minute light exposure. This system had the advantage of requiring only two readings, a point of possible importance when the shaking was to be interrupted for each reading.

Photosynthesis can also be computed by making measurements at C and D, as well as at A and B. The rate of pressure change in the light, measured from C to D, can then be corrected with the respiration rate from A to B. Rieke compared the efficiency obtained in this way with the efficiency obtained by Warburg and Negelein's method and found that the latter gave higher yields, a point which may have played a part in their choice of readings. We can confirm Rieke's finding and can show why Warburg and Negelein's periods lead to higher yields. Both the sudden burst of pressure immediately after the light is turned on at B and the low rate of pressure change between D and A tend to raise the computed photosynthesis. The respiration measurement from A to B is the same in both cases and usually includes the maximum deviation of the dark pressure change from the steady rate. The effect of this deviation can be avoided by waiting to make the respiration reading until after the rate has returned to a nearly constant value. For example, the period E to F might be used. But the rate continues to decline slowly in the dark, so that the selection of a period in which to make measurements is still arbitrary; and the longer the time between the light period and the respiration measurement, the more likely it is that the measured rate does not represent the rate of respiration during the light.

Another method of computing the pressure change due to photosynthesis, which should give the same result if there were no deviations, is to measure the average pressure change for five minutes of light from two successive C-D periods, multiply by three, and compare with the pressure change for the intervening 15-minute period D to C, which includes 10 minutes of darkness. In general this leads to a lower value for the efficiency than the other two methods; for the burst of pressure in the light, included in the period D to C, now has the effect of lowering the

respiration reading.

A comparison of the values for two light intensities resulting from four different methods of computation is given in table 5. The differences between these figures bring out the importance of the deviations even at the low light intensities used for measuring maximum efficiency. Until further information is available, it appears to us that the selection of any particular method of computation must be largely arbitrary. This conclusion inevitably tends to lessen

Table 5. Dependence of computed quantum yield on method of computation for two intensities: 350 ergs/cm.2/sec., ordinarily used for efficiency measurements; and 1400 ergs/cm.2/sec., used for figure 2. Letters designating method of computation correspond to those in figure 2.

C-D	$\mathbf{E}\mathbf{-F}$	.206	.151					

the significance which has been attributed to the grouping of Warburg and Negelein's quantum yields for red and yellow light around the theoretical maximum of 0.25.

Moreover, in this connection it must be pointed out that their system of measuring light intensities involved use of the bolometer in a vertical position, whereas it was calibrated in a horizontal position. Our bolometer, similar in construction to theirs, shows about 12 per cent greater sensitivity in the vertical than in the horizontal position. If their instrument had the same dependence of sensitivity upon position, it would mean that their measurements of light intensity were about 12 per cent too high and their quantum yields 12 per cent low. The values then would no longer be so closely grouped around 0.25.

The third question raised at the beginning of the paper, whether the measured values truly represent the quantum yield of the assimilatory apparatus, must for the present be answered in the negative, because the observed deviations from expected pressure change indicate departures of  $\gamma$  from unity. The manometric method, as it has been applied to the measurement of photosynthetic efficiency, is based, as we have explained, on the assumed constancy of y. In view of the apparent variability in y disclosed by our results, measurements made in this way cannot be accepted as significant until the method has been applied in such a way as to permit the simultaneous determination of both carbon dioxide and oxygen exchange. Yields higher than 0.25 may be due only to incorrect interpretation of measurements, the first alternative mentioned at the beginning of Part II. But correct interpretation of the measurements, based on determinations of the value of  $\gamma$ , may still result in quantum yields appreciably higher than 0.25. For this reason it seems necessary to consider the second alternative, that the chemical changes actually involved are different from those assumed to take place. As explained in the introduction to Part II, the theoretical maximum yield of 0.25 is based on the assumed synthesis of carbohydrate from carbonic acid.

The chemical mechanism of photosynthesis.—The commonly accepted value of unity for the ratio of exchange of carbon dioxide and oxygen (obtained as a rule from measurements of longer duration than

the efficiency measurements) has been regarded as evidence that intermediate substances less reduced than carbohydrate do not accumulate during photosynthesis. As a result of unsuccessful attempts to make *Chlorella* cells synthesize carbohydrates from possible intermediate substances, Warburg (1925, p. 402–403) believed that such substances probably played no part in photosynthesis. Probably for these reasons, Warburg and Negelein felt justified in regarding their measurements of efficiency as representing the complete synthesis of carbohydrate from carbon dioxide and water.

Our own observations, as set forth in the discussion of figure 2, are a clear indication that the ratio of exchange of carbon dioxide and oxygen departs from unity during the short light exposures used for efficiency measurements. If, as still remains to be shown, the deviations in y are indeed connected with photosynthesis, then it will be necessary to reconsider the possible rôle of intermediate products. The departure from unity of the value of y for photosynthesis suggests the temporary accumulation or disappearance of substances less reduced than carbohydrate. If during short light exposures carbon dioxide were only partially reduced, or if carbohydrate were formed from partially oxidized intermediates of respiration (a possibility recognized by Warburg, 1920, p. 205), then large deviations in  $\gamma$ would be anticipated. Such syntheses might require appreciably less energy than complete synthesis of carbohydrate from carbonic acid. Yields as high as are indicated by our present figures may be quite consistent with reaction mechanisms of this type. The efficiency measured over short intervals may considerably exceed the theoretical maximum for complete carbohydrate synthesis, which presumably becomes the dominant process only after a period of illumination sufficiently prolonged so that photosynthesis has reached a stationary state, and all steps in the process are proceeding at the same rate.

Part III. Experimental details.—The technique of culturing.—The organism used was Chlorella pyrenoidosa, isolated in 1926 from Berlin tap water and maintained since then on mineral agar slants exposed to daylight at a north window. A stock suspension of cells was obtained by inoculating a liquid culture with a mass of cells transferred from an agar slant with a needle. This liquid culture

was then grown at a temperature of about 20° with continuous illumination from a tungsten filament lamp (100-watt bulb at 20 cm.). After five to ten days' growth, when the culture had attained a moderate density, the concentration of cells was determined by centrifuging a sample into a calibrated capillary tube. The stock suspension usually contained from one to two mm.<sup>3</sup> cells per ml. of fluid. It was stored in the refrigerator and used for the inoculation of liquid cultures in which material for the efficiency measurements was grown. When exhausted, the stock suspension was replaced by another, again produced by growing a liquid culture inoculated directly from an agar slant.

The liquid cultures were grown in flasks of the usual pattern. These were made from 300 ml. Erlenmeyer flasks, by sealing inlet and outlet tubes for gas circulation into the sides of the necks. The tops, instead of being sealed over, were left open for greater convenience in filling and inoculation. The flasks were filled with the medium (200 ml. per flask), plugged with cotton, sterilized, and inoculated from the stock suspension, 5 ml. of stock being transferred to each culture with a sterile pipette. The cotton-plugged tops were then covered with tight-fitting rubber caps, so that a series of flasks could be connected to a single gas stream in the usual way.

The inoculated flasks were stored in the refrigerator and set out to grow in the illuminated culture baths as frequently as material was required for experimental work. Storage of the stock suspension or of the ungrown cultures in the refrigerator for periods of several weeks seemed to have no effect on the metabolism of the cultures after reaching maturity. The mature cultures, however, could not be stored in the refrigerator, even for a few hours, without suffering a decrease in photosynthetic efficiency, although storage up to several days has been found to be without effect on the maximum rate of photosynthesis.

During growth the culture flasks stood in a stream of running water in shallow glass dishes accommodating four flasks each. The desired temperature, usually 20°, was maintained within about 2°. Illumination 24 hours a day was provided by internally frosted tungsten filament lamps located below the glass dishes. For most of the work described in this paper, 100-watt lamps were used without reflectors, and the intensity of illumination was varied by changing the distance of the lamp, rather than the watt rating. One lamp was used for each dish of four culture flasks. The distances specified in the text are from the top of the lamp to the bottoms of the culture flasks. The cultures were aerated with a slow stream of 5 per cent carbon dioxide in air. The cells settled slowly to the bottom of the flasks, and were stirred up by gentle shaking twice daily.

The culture medium was of the following composition:  $MgSO_4$ , 0.0100 molar;  $KNO_3$ , 0.0125 molar;  $KH_2PO_4$ , 0.0090 molar;  $Fe_2(SO_4)_3$ , 0.000005 molar or 0.000025 molar;  $CaCO_3$ , 0.00001 molar.

The stock solutions were stored in Pyrex bottles cleaned with hydrochloric acid and rinsed only with glass distilled water. Merck's reagent grade chemicals were dissolved in glass distilled water. This was obtained by redistilling the laboratory distilled water, which was from a tinned still, in an all-Pyrex still designed to give good counter current washing of the ascending vapor.

Stock solutions: A. MgSO<sub>4</sub>7H<sub>2</sub>O, 50 g./liter; B. KNO<sub>3</sub>, 25 g./liter; C. KH<sub>2</sub>PO<sub>4</sub>, 25 g./liter; D. Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, 4 g./liter; E. CaCO<sub>3</sub> (suspension), I. g./liter

To prepare culture medium, 50 ml. each of stocks A, B, and C were mixed and made up to one liter with the desired kind of water. Then either 0.5 or 2.5 ml. of solution D were added, depending on the iron concentration desired. The calcium carbonate suspension was shaken and one ml. added per liter of medium.

Under some conditions the efficiency was found to be higher in media containing calcium carbonate, so it was regularly included in the medium, although no experiments were made to show whether the improved efficiency was due to the calcium or to impurities. Warburg and Negelein added no calcium because it was present in the tap water they used to prepare the medium. Rieke, using distilled water, specified the addition of calcium nitrate. But Chlorella, unlike higher algae, seems to require no calcium for normal growth (cf. Pringsheim, 1926; Trelease and Selsam, 1939), and its presence may not be necessary for high efficiency of photosynthesis.

The filling of the manometer vessels.—To prepare cells for measurement of efficiency, they were centrifuged out of the culture medium, washed twice in freshly prepared medium, and made up to 28 ml. in medium saturated with 5 per cent carbon dioxide in air. Three ml. were used to determine the concentration of cells in the suspension, by centrifuging to constant volume in a calibrated capillary tube. The remaining 25 ml. were pipetted into the manometer vessel, and 3 ml. of medium added, bringing the total fluid volume to 28 ml. Ordinarily, medium with high iron concentration prepared in glass distilled water was used as suspending fluid for the experimental work, regardless of the medium in which the cells had been grown. However, in cases where higher concentrations of the major nutrient salts had been used for culturing the cells, the same concentrations were used for the measurements of photosynthesis, to avoid subjecting the cells to changes in osmotic pressure.

The manometer and vessels were similar to the apparatus described and illustrated by Warburg (1926, p. 1). After the vessels had been filled and connected with the manometer, the gas spaces were flushed out with 5 per cent carbon dioxide in air. The vessel containing the cells was then covered with a jacket of thin sheet brass with aluminum lining to reflect back into the cell suspension any light scattered out at the sides. This replaced the silvering and copper plating used by Warburg and Negelein.

A circular hole in the bottom of the jacket exposed almost the entire area of the bottom of the vessel to light, and served to define the area of cross section of the light beam admitted, which was 15.4 cm.<sup>2</sup>.

The measurement of photosynthesis.—For making the measurements, the vessels were submerged in a large water bath the temperature of which was maintained constant within a few hundredths of a degree, and the manometer yoke was connected to the shaking apparatus, an eccentric ball, the speed of rotation and eccentricity of which could be varied over a considerable range. Rapid mixing of the cell suspension is important. We found that an eccentricity of 4.3 mm. and a speed of 550 r.p.m. gave satisfactory results. Mixing was greatly improved by the use of a paddle-like extension of the vessel stopper, which projected downward at an angle into the suspension near the side of the vessel, adding turbulence to the rapid rotary motion of the liquid.

Pressure changes were measured without interrupting the shaking of the manometer and vessels, by reading the level of the manometer fluid (isocaproic acid) in both arms of the differential manometer simultaneously with a double cathetometer reading in hundredths of a millimeter. Random fluctuations in the readings varied from one or two hundredths of a millimeter to as much as one-tenth of a millimeter. There were occasional greater irregularities in the pressure changes, some of which seemed to be caused by slight changes in the temperature of the manometer fluid. These were minimized by protecting the manometer from air currents with a glassfronted box through which readings were made. Other irregularities appeared to originate inside the vessel, possibly from the random formation and breaking of bubbles in the agitated cell suspension. In our experience, the use of paraffin oil, recommended by Warburg and Negelein for the control of bubbles, has been of little or no value, so we omitted it in most of our work. The good agreement of the efficiency from successive light exposures showed that random irregularities in the pressure readings caused no appreciable error. The first measurement was always discarded, and the average photosynthesis from the next two or more light exposures was taken as the final value.

Light source and optical system.—A 10,000-lumen sodium vapor lamp (type Na9, obtained from the General Electric Vapor Lamp Co.) was used as a source of illumination. By enclosing the lamp in a wooden housing and running it above normal operating temperature, the light from the central region of the lamp was kept very uniform in intensity and practically free from neon lines. The infrared was removed by a 4.5 cm. layer of 1.65 per cent copper sulfate. This also served to reduce the very small amount of visible red neon radiation. Wave lengths shorter than the sodium line were of negligible intensity, but were sometimes removed by a yellow glass filter (Corning "yellow-yellow," No. 351).

A condenser was illuminated with the central area of the lamp. An image of this lens was projected by

a second lens and reflected vertically through a glass window in the water bath onto the vessel containing the cell suspension. The maximum available intensity was about 6500 ergs/cm.<sup>2</sup>/sec. This could be reduced by introducing calibrated diaphragms at the second lens. Photosynthesis measurements could be easily made down to 200 ergs/cm.<sup>2</sup>/sec.

Measurement of input radiation.—The energy was measured by projecting the beam of light horizontally onto a measuring instrument (bolometer, thermopile, or photronic cell) instead of into the cell suspension. This was done without disturbing the train of lenses and filters, by rotating about the axis of the beam the 45° mirror which served to reflect the light into the vessel. To maintain the similarity of the two optical paths, a window similar to the multiple window of the tank was placed in front of the measuring instrument. There remained the difference in the paths due to the layer of water and the vessel window, for which correction was made by multiplying the measured energy by 1.028. The bolometer diaphragm admitted a light meam 21 by 22 mm. in cross section. The surface of the thermopile was 1 × 10 mm. These instruments were calibrated against radiation standards from the National Bureau of Standards. The latter were operated on direct current and controlled with the help of a potentiometer and standard cell, by which both the current and voltage could be measured. The potentiometer was also used to measure the voltage applied to the bolometer and the compensating e.m.f. with which its circuit was balanced. The Weston photronic cell was mounted at the back of a small box with white inside walls. Light was admitted to the box through an opal glass window opposite the photocell, with a diaphragm equal in area to the one admitting light to the cell suspension. To insure linearity of response, the resistance of the electric circuit was kept down to 5 ohms. This combination was calibrated against the bolometer and thermopile in uniform parallel light from the sodium lamp. The three instruments gave results agreeing in most cases within a per cent at the lower intensities. At the higher intensities the beam was too sharply convergent for accurate measurement except by the photronic cell.

Intensity measurements were also made with the photronic cell placed in the water bath, in the same position occupied by the cell suspension. After proper corrections were made for reflection losses, these measurements were in good agreement with those made with the measuring instruments outside the tank. A few efficiency measurements were made with a beam of small enough cross section so that both the vessel and the measuring instrument could admit the entire beam. The results were in agreement with the other system of illumination.

Correction for incomplete light absorption.—Ordinarily efficiency measurements were made with a suspension of cells sufficiently dense to absorb all

the light entering the vessel, so that no provision was made for accurate measurement of the light transmitted. However, in measuring the dependence of the efficiency upon the culture medium, as in tables 1 and 2, it was considered desirable to harvest the cultures as nearly as possible at the same age. In several cases this resulted in cultures which failed to provide enough cells to give complete absorption of the incident light. By observing visually the light transmitted by the suspension during agitation in position for measurement of photosynthesis, a rough estimate was made of the percentage absorption. This percentage of the measured incident radiation was used in computing the efficiency. The estimated absorption for each culture is given in the tables as an indication of the error that may have arisen from this source in the determination of the efficiency.

Under standardized conditions, such as optical system and intensity, it was found that independent absorption estimates by two observers agreed within 5 per cent on an arbitrary scale. This scale was fixed partly by observing the beam of sodium light through neutral filters of known transmission and by making allowance for scattering by the cell suspension. The accuracy of our arbitrary scale of absorption was tested by measuring efficiency with three concentrations of similar cells, which were estimated to absorb 85, 98, and 100 per cent of the incident light. The resulting efficiencies, corrected for these absorption values, were 0.322, 0.325, and 0.322. This agreement, though doubtless partly fortuitous, indicates that our arbitrary scale was fairly accurate. If we allow the possibility of an error of one third in our estimate of the transmitted light, then the corresponding uncertainty in the absorption would be 6 per cent for an absorption of 85 per cent, and 11 per cent for an absorption of 75 per cent. In the majority of our efficiency measurements this error was negligible, since the estimated absorption was between 95 and 100 per cent. Admitting the unsatisfactory character of visual estimations of light absorption, we feel confident that the error introduced in this way is not sufficient to alter the conclusions drawn from the various tables.

Computation of photosynthesis and efficiency.—
The amount of carbon dioxide assimilated was computed by multiplying the pressure change due to photosynthesis by a factor designated as the vessel constant. The derivation of this constant is explained by Warburg (1926, p. 8–11, 114). We give below the necessary data for the computation of one of our own vessel constants.

 $P_{o} = 11,180$  mm., normal pressure in mm. of isocaproic acid.

T = 283°K, temperature of vessels.

v<sub>G</sub> = 17,130 mm.3, gas volume in experimental vessel.

v<sub>F</sub> = 28,000 mm.3, fluid volume in experimental vessel.

 $v'_{G} = 16,490$  mm.3, gas volume in compensation vessel.

 $v'_{E} = 28,000 \text{ mm.}^3$ , fluid volume in compensation vessel.

A=0.265 mm.2, area of cross section of manometer capillary.

 $a_{\text{CO}_2} = 1.188$ , Bunsen absorption coefficient for carbon dioxide in the liquid medium.

 $\alpha_{00} = 0.038$ , Bunsen absorption coefficient for oxygen.

 $\alpha = 0.06$ , Bunsen absorption coefficient for the gas in the compensation vessel.

 $\gamma = -0.9$ , ratio of exchange,  $CO_2/O_2$ , in photosynthesis.

By the formula given by Warburg, these values lead to  $k_{O_2}=1.838$  and  $k_{CO_2}=4.953$ . The vessel constant for oxygen is then  $k_{CO_2}\,k_{O_2}/(k_{CO_2}+\gamma\,k_{O_2})=2.76$ . The oxygen is used as a measure of the amount of carbon dioxide reduced, on the basis of considerations explained in detail by Warburg and Negelein (1922, part III).

Certain of these quantities call for some comment. The volumes of the vessels and connecting gas spaces were determined by filling them with mercury and weighing the mercury. Successive determinations agreed within about one hundredth of a per cent.

The value of  $a_{CO_2}$ , the Bunsen absorption coefficient for carbon dioxide, may not be the same for the fluid used in our vessels as the tabulated value for pure water. Warburg made a correction for this on the basis of measurements of Geffken. We made measurements of  $\alpha_{CO_2}$ , both for the pure water and for the culture medium used as suspending fluid. We were able to check the tabulated values for pure water at 0°, 8°, and 22° within about 1 per cent. Our values for culture medium, measured at the same temperatures, were between 0.8 and 2.0 per cent lower than for pure water, the same order of magnitude as the 1 per cent correction used by Warburg and Negelein. Since the salt concentration of our medium was half as great as theirs, we thought it justifiable to use a smaller correction factor for  $\alpha_{\text{CO}_2}$  and made a uniform correction of 0.5 per cent in the tabulated values at all temperatures (Landolt-Boernstein, 1912, p. 599). This correction slightly lowers the computed efficiencies.

For  $\gamma$ , the ratio  $\mathrm{CO_2/O_2}$ , we have used —0.9. As explained in Part II, there are reasons for questioning the constancy of  $\gamma$  over the short periods used for measuring efficiency. But since we have as yet no information from which a more correct value could be derived, it seems justifiable to adhere to their figure, if only to keep our results comparable with theirs.

Sample experiment.—The efficiency at low intensity for the sixth culture in table 3 was calculated from the following readings, which are differences in millimeters between the levels in the two arms of the manometer. The times are designated by letters which correspond to those in figure 2. The first cycle of light and dark is omitted.

Light	t Time		Reading	Difference
	A	2:55	15.83 լ	4.10
On	В	3:00	19.93 ₹	1.10
	$\mathbf{C}$	3:05	22.10	7.58
Off	D	3:10	23.96	1.00
	$\mathbf{A}$	3:15	27.51	0.00
On	В	3:20	31.49	3.98
	C	3:25	33.52	<b>*</b> 0.0
Off	D	3:30	33.41	7.36
	$\mathbf{A}$	3:35	ر 38.85	4.00
	В	3:40	42.87	4.02
	$\mathbf{E}$	3:45	46.73	3.71
	F	3:50	50.44	3.11

Computation of the pressure change due to photosynthesis by Warburg's method, described in Part II, was made as follows:

	Second cycle	Third cycle
5 min. dark A-B	4.10	3.98
5 min. dark A-B	3.98	4.02
5 min. dark, average	4.04	4.00
15 min. dark	12.12	12.00
10 min. light, 5 min. dark	7.58	7.36
Difference	4.54	4.64
Average pressure change due to 10 min. light	4.59	mm.

The vessel constant for oxygen in this case was 2.691 mm.  $^3/\text{mm}$ . Therefore the oxygen produced due to 10 minutes of light was  $4.59 \times 2.691 = 12.35 \, \text{mm}$ .  $^3$   $O_2$ , or  $12.35 \times 6/22.4 \times 10^6 = 3.31 \times 10^{-6}$  moles  $O_2/\text{hr}$ . Each mole of oxygen is assumed to represent the reduction of one mole of carbon dioxide. From the heat of combustion of glucose, the energy stored was  $3.31 \times 10^{-6}$  moles  $CO_2/\text{hr}$ .  $\times$  112,000 cal./mole  $CO_2 = 0.371 \, \text{cal./hr}$ .

The light intensity was measured with the photronic cell, which gave the following galvanometer deflections: 28.8 mm. at 2:55, 28.4 mm. at 3:15, 28.3 mm. at 3:35. Calibration of the photronic cell gave 12.56 ergs/cm.²/sec. per millimeter deflection, so that 28.4 mm. corresponds to an intensity of 357 ergs/cm.²/sec. The area of the vessel diaphragm was 15.4 cm.², and the window correction was + 2.8 per cent, so that 5650 ergs/sec. entered the vessel. Since the estimated light absorption in this case was 98 per cent, the radiant energy absorbed by the cells

was 5530 ergs/sec. One mole quantum, or einstein, at the wave length used ( $\lambda = 589.2 \text{ m}\mu$ ) is equivalent to Nh $\nu = 2.021 \times 10^{12}$  ergs. The energy absorbed was therefore 5530 ergs/sec. = 0.476 cal./hr. =  $9.85 \times 10^{-6}$  mole quanta/hr.

From the above figures, the efficiency of photosynthesis may be expressed as 0.371 cal./hr. stored  $\div$  0.476 cal./hr. absorbed = 78.0 per cent, or as  $3.31 \times 10^{-6}$  moles CO<sub>2</sub> reduced per hr.  $\div$  9.85  $\times$  10<sup>-6</sup> mole quanta absorbed per hr. = 0.336 (moles CO<sub>2</sub>/mole quantum) = 0.336 (molecules CO<sub>2</sub>/quantum).

#### SUMMARY

Using the manometric method developed by Warburg and Negelein, we have studied the dependence of the quantum yield of photosynthesis in *Chlorella pyrenoidosa* on various factors. High yields are favored by the presence of traces of certain heavy metals in the culture medium. The conditions during growth of cultures, and during measurement of photosynthesis, also influence the apparent quantum yield. With favorable combinations of conditions, yields as high as 0.33 molecule of carbon dioxide per absorbed quantum have been obtained, with indications that still higher efficiencies are possible.

A yield of 0.25 has heretofore been regarded as close to the theoretical maximum, because it has been believed that photosynthesis represents the complete synthesis of carbohydrate from carbon dioxide and water. If appreciably higher yields are obtainable, we must consider the possibility that some less complete synthesis may take place. This would involve a change in the usual ratio of unity for the exchange of carbon dioxide and oxygen. The behavior of the pressure change observed during the short periods of light and darkness used for measuring efficiency indicates that there are large variations in the ratio of exchange of oxygen and carbon dioxide.

Since the computation of photosynthesis from measurements of pressure change is based on the assumed constancy of this ratio, we conclude that the efficiencies obtained from the usual manometric measurements are subject to certain errors and may not represent the true efficiency of the assimilatory apparatus.

# NATURE OF GROWTH DIFFERENCES IN TWO SORGHUM VARIETIES. I. INFLUENCE OF PRELIMINARY SOAKING ON EARLY GROWTH AND AUXIN CONTENT 1

# Robertson Pratt and Harry G. Albaum

The study of physiological differences among varieties of a single species is not only an interesting field of investigation but it may yield important information concerning the mechanisms of different processes. The present paper is the first of a proposed series dealing with differences in two varieties of Sorghum vulgare—namely, Standard Yellow Milo and Dawn Kafir. Experiments performed independently by the authors revealed striking differences in the early growth rates of these two varieties, seedlings of the former grown in the dark developing much more rapidly and being much sturdier than those of the latter. The results of the experiments suggested a hormonal interpretation and led to the work reported herewith.

Methods.—Pure strains of Sorghum vulgare (varieties Standard Yellow Milo and Dawn Kafir) were used throughout these experiments.<sup>2</sup> All water used in the growth experiments was distilled twice, the second distillation being carried out entirely in Pyrex apparatus.

In each experiment, unless otherwise indicated, groups of 35 seeds were soaked in 50 cc. of distilled water, each lot of seeds being transferred to fresh 50 cc. portions of water hourly for six hours, and then every twelve hours, as long as soaking continued. After soaking they were placed, embryo side up, on three layers of moistened filter paper in Pyrex Petri dishes. When the roots were about 5 mm. long, 25 representative seedlings were transferred with clean forceps to perforated cork discs previously coated with paraffin. The roots protruded through the holes and into the distilled water on which the corks floated, each in a separate beaker. The seed-

<sup>2</sup> Seeds were kindly furnished by Dr. G. M. Reed and Dr. D. E. Marcy of the Brooklyn Botanic Garden.

lings were carefully removed at suitable intervals, root and shoot lengths were measured with a millimeter scale, and the seedlings were replaced on the discs. Thus, measurements were obtained on the same sets of seedlings throughout each experiment. The plants were in the dark at all times except while the water was changed and measurements were made, at which times they were exposed to weak, diffuse light from a Mazda lamp.

Some of the quantitative differences in the growth experiments may have been due to fluctuations in the temperature, which varied from 18°-25°C. The general trend was the same in all experiments, however.

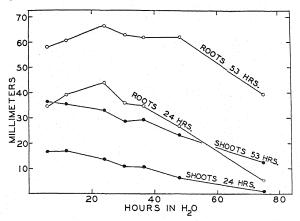

It is improbable that the effects observed in these experiments were due to poor aeration, because the results were essentially the same when the water was continuously aerated while the seeds were immersed in it. Furthermore, germination, as indicated by the initial protrusion of primary roots, occurred readily in completely submerged seeds of both varieties.

RESULTS.—The experimental procedure seemed to exert little, if any, effect on the growth of Dawn Kafir seedlings but markedly influenced the growth of the Yellow Milo variety.

The pronounced effect on Yellow Milo seedlings is shown in figure 1, in which data from a typical experiment are presented. The mean length of roots and shoots (internodes plus coleoptiles) at different times is plotted on the ordinate scale and the length of the soaking period on the abscissa. The shoot length was always inversely related to the duration of the previous period of soaking. Root growth, on the other hand, increased as the period of soaking increased up to 24 hours but was retarded by longer immersion.

The results suggest that when Milo seeds are soaked in water a substance that may be tentatively identified as an auxin or its precursor leaches out of the seeds or is inactivated or destroyed. Data presented below indicate that the observed effect was probably due in large measure to auxin's being leached out of the seed.

Experiments have indicated that, in some plants at least, the optimum auxin concentration for root growth is lower than for shoot growth (Thimann,

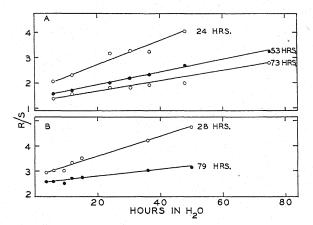

Fig. 1 (above). Mean length of roots and shoots of Sorghum vulgare var. Yellow Milo at different times after different initial periods of soaking in water.

Fig. 2 (below). Mean length of root in relation to that of shoot (R/S) in seedlings of  $Sorghum\ vulgare\ var.$  Yellow Milo at different times after different initial periods of soaking in water.

1937; Kaiser and Albaum, 1939). Removal of some of the auxin, or its precursor, might therefore be expected, under certain conditions, to retard the growth of shoots relatively more than that of roots; and, indeed, it is readily conceivable that extraction of some of the hormone would bring about an increase in the growth of roots while causing a decrease in shoot growth. The data presented by the curves in figure 1 are in agreement with this hypothesis and may be interpreted to mean that during the

soaking period an auxin or some related compound diffused out of Yellow Milo seeds and that after approximately 24 hours the supply within the seeds was reduced to the optimum level for root growth under the experimental conditions. They also seem to indicate that with further soaking, the amount of auxin present in the seed was reduced to such a low level that it became limiting for root growth as well as for shoot growth. Longer periods of soaking, therefore, brought about a decrease in the length of both organs. According to this idea, the amount of auxin initially present was sub-optimal for the growth of shoots. Therefore, the size of these organs decreased even with the shortest periods of immersion.

The failure of Dawn Kafir seedlings to respond to the experimental treatment may indicate that it was impossible under the conditions of these experiments to reduce the hormone content sufficiently to cause any appreciable change in growth, either because the seed coats of this variety are relatively impermeable to auxins or because there is a high degree of auxinsatiety.

Figure 2 shows the mean length of the primary root in relation to that of the shoot (R/S ratio) in Yellow Milo seedlings at different times after different periods of soaking. The two upper curves in figure 2A are derived from the data in figure 1; those in figure 2B represent the averages obtained from three later experiments. At different times during the course of the experiments, the value obtained when the mean length of the primary roots was divided by that of the shoots increased with the length of time the seeds had previously been soaked. Although the points are somewhat scattered, the curves seem to be approximately linear over the period of time covered in these experiments. That the effect of soaking the seeds was most pronounced in the very early stages of development is shown by the higher levels and greater slopes of the curves for shorter periods of growth. The important point for the present discussion is that in any one curve the root/shoot ratio increases with the length of the previous soaking period. This indicates that shoot growth was retarded relatively more than rootgrowth as the preliminary period was extended.

Table 1. Influence of soaking seeds in water on the subsequent root/shoot (R/S) ratios in Yellow Milo and Dawn Kafir seedlings grown in distilled water in the dark.

Hours	R/S at	R/S at 24 hrs.a		53 hrs.a	R/S at 73 hrs.a	
soaked	Milo	Kafir	Milo	Kafir	Milo	Kafir

75.0	5.35	3.27	3.22	2.80	2.80	2.24

a Hours from the time seedlings were placed on corks.

Data from a typical experiment are presented in table 1 and clearly demonstrate the pronounced difference in the effect of soaking on the two varieties of seeds. Note that while the values for Milo steadily rise in each column, those for Kafir show no consistent tendency to either rise or fall, indicating that roots and shoots were about equally affected or were not affected at all by the soaking treatment.

Results of other experiments also support the hypothesis that the response of Yellow Milo seedlings to prolonged soaking is due, in part at least, to partial depletion of the supply of an auxin or some related compound.

If the effects recorded above were due to loss of an auxin, frequent changing of the water in which the seeds were soaked would be expected to facilitate its removal, and prolonged soaking in a very small volume of water that is not changed might be expected to cause relatively less decrease in shoot growth and relatively greater decrease in root growth than soaking in an equal volume of water with numerous changes. In other words, frequently changing the water in which the seeds are soaked should tend to increase the root/shoot values. Accordingly, the following experiment was performed.

A group of fifty Milo seeds was placed in each of two small vials, and enough water (2.5 ml.) was added to just barely cover the grains.<sup>3</sup>

In one group ("C") the water was withdrawn by means of a pipette, and fresh water was added hourly for the first 8 hours, and then at 8-hour intervals for the next 40 hours. The water of the other group ("U") was not changed during the 48 hours that the seeds were soaked; as they swelled, suffi-

a Hours from the time seedlings were placed on corks.

cient water was added to keep them just barely submerged at all times. After 48 hours' immersion, both groups of seeds were placed on filter paper in the usual way and were transferred to corks 34 hours later. Nearly all seeds in both groups had germinated and had roots about 1 mm. long at the end of the soaking period. At that time about two-thirds of the seeds in the "U" series had shoots ½-1 mm. long. Shoots were not apparent on any seeds of the "C" series. This experiment was repeated twice, and the figures obtained are presented in table 2. It may be seen that the data are in good agreement with expectations based on the hypothesis outlined above.

In another experiment, one hundred seeds of each variety were soaked in 100 ml. of water for 40 hours. and after removal of the seeds the water from each group was evaporated under reduced pressure at 65-70°C. to approximately 1 ml. These 1 ml. samples were then thoroughly mixed with equal portions of lanolin, and the resulting pastes were applied to the upper surfaces of petioles of young leaves of Atropa belladonna. Twelve hours later epinastic curvatures had resulted in 6 of 12 petioles treated with Milo extract, but none of those treated with Kafir extract had responded. This experiment was not repeated, and it is not entirely satisfactory, since it does not tell whether the lower auxin content (or its absence) in the Kafir extract was due to impermeability of the seed coats or to a smaller amount of auxin present in the seeds.

It seemed desirable to determine the relative amount of auxins in each variety of seed after treatment similar to that used in the growth experiments. Accordingly, different lots of seeds of the two varieties were soaked in small quantities of water for 30 hours, the water of one group of seeds ("C") of each variety being changed hourly for the first 8 hours and then less frequently and that of the other group ("U") remaining unchanged during the entire period of soaking.

The seeds were then extracted with chloroform according to the method of Thimann (1934), and the extracts were tested for the presence of auxins by means of the usual Avena-coleoptile curvature method. The oat variety, Victory, was used for these tests, and the double decapitation method described by Went and Thimann (1937) was employed. Ten to twenty test plants were used in each experiment, and shadowgraphs were made 90 minutes after application of the agar blocks.

3	6.2°	4.5°	0.72	10.7°	9.3°	0.87

<sup>&</sup>lt;sup>a</sup> Twenty-five seeds extracted for each series.

<sup>&</sup>lt;sup>3</sup> Since Kafir seeds were not responsive to the soaking treatment, only Milo seeds were used.

The results of tests repeated on different days are shown in table 3. The test plants used in the third trial were about 24 hours older than those used in the first and second trials and were less sensitive. However, although the magnitude of response was reduced, the relative response to the extracts from the "unchanged" and "changed" series was not significantly different from the earlier tests. The data in table 3 seem to show rather clearly that the Kafir seeds are less permeable to auxins than Milo seeds, since frequently changing the water, presumably maintaining thereby a steep concentration gradient from internal to external solution, caused greater loss of auxin from Milo than from Kafir seeds. It should be borne in mind that extremely small volumes of water were employed. Similar results probably could not be so easily detected with large volumes of water, since it is doubtful that the hormone concentration in the external medium would become sufficiently great to markedly inhibit its outward diffusion. Column 4 shows that approximately 70 per cent as much auxin was present in Milo seeds when the water was frequently changed as when it remained unchanged, but the corresponding value for Kafir seeds was about 90 per cent (column 7).

It is apparent from the figures in table 3 that frequently changing the water in which the seeds were soaked caused relatively greater loss of auxin from Milo seeds than from Kafir and that after the soaking period, whether the water was changed or unchanged during the period of immersion, Kafir seeds contained more of the compound than did Milo. It should be noted, however, that in the dry condition, before soaking, seeds of the two varieties contained approximately equal quantities of the hormone (table 4, column 3).

Comparison of tables 3 and 4 shows that the auxin content of Kafir seeds increased considerably during the soaking period, and although the available data are not adequate to tell whether or not there was an increase in Milo seeds also, it seems reasonable to assume that the preliminary stages of germination would follow the same course in both varieties of *Sorghum*. Thus it appears likely that two factors are involved in these experiments—i.e., permeability of the seed coats to auxins and rate of

hormone production. The possibility should not be ignored, however, that the rate of auxin production may be the same in both varieties and that the apparent greater speed in Kafir seeds is merely due to the accumulation of hormone that cannot escape through the seed coat of this variety as readily as through that of Milo seeds. In order to learn about the total amount of auxin formed it would be necessary to assay not only the seeds, but also the water in which they were soaked. This was not done, except indirectly in the petiole-bending tests referred to above. It should also be pointed out that escape of auxin from seeds may depend upon its location within the seeds and that the proportion of auxin or its precursor in the embryo and endosperm, respectively, may influence their outward diffusion.

The data so far considered concern the amount of auxin present in the two varieties of seeds but tell nothing about its concentration, a factor which might be of considerable importance in determining growth rates. To obtain a true picture of the relative concentrations of auxins in the two varieties of seeds, it is necessary to make a correction in the observed figures because of the difference in size and weight, Milo seeds being larger and about 30 per cent heavier (air dry weight) than Kafir. The data for the "unchanged" seeds (M. U. and K. U.) in table 3 have been treated accordingly, and the corrected figures are given in table 5. The data in table 4 have also been treated in the same manner, and the corrected figures are shown in column 4.4 The last column in each table affords a measure of the rela-

Table 5. Avena curvature per gram extracted material.

Data from table 3. See text for explanation.

	Curvature		
Test number	M. U.	K. U.	M. U./K. U.

a Twenty-five seeds extracted for each test.

tive auxin concentration (not total content) in the two varieties. It may be seen that in the dry condition, before soaking, the auxin concentration in Yellow Milo seeds was about 70-80 per cent as great as in Kafir seeds (table 4, last column) but that after soaking for 30 hours under the conditions of these experiments, the hormone concentration, as measured by degrees of curvature induced per gram of extracted material, was about 40-45 per cent as great in Milo seeds as in Kafir (table 5, column 4).

This enormous difference in hormone concentration may be an important factor in determining the rate of early growth of these two varieties of Sorghum. If this proves to be so, it will be an interesting example of the determining influence of natural differences in hormone concentration on the growth and development of plants. Van Overbeek (1935) has shown that in corn, stunting of the dwarf variety, Nana, may be due to a natural deficiency of available auxin, the supply in the plant being destroyed by enzymatic action. It is believed that the present case—i.e., the relatively puny early growth of Dawn Kafir seedlings, may represent a tendency in the other direction—i.e., a plant which grows slowly, because it contains a surplus of auxin, and is not able to destroy or eliminate the excess. Further experiments are being planned to test this hypothesis.

#### SUMMARY

Seeds of Sorghum vulgare, varieties Yellow Milo and Dawn Kafir, were soaked in distilled water for different lengths of time. After germination had occurred, they were placed on perforated corks arranged so that the roots dipped into distilled water, and the subsequent growth of roots and shoots (internodes plus coleoptiles) was observed for 2-3 days.

The growth of Dawn Kafir seedlings was not appreciably affected by the different treatments, but that of Yellow Milo was markedly altered.

The shoot length at any time was inversely related to the duration of the previous period of soaking. Root-growth, on the other hand, increased as the period of previous soaking increased up to 24 hours but was retarded by longer periods of immersion.

The ratio obtained when the mean root length at any time was divided by the mean shoot length at the

same time increased as the previous period of immersion increased, indicating that shoot growth was retarded relatively more than root growth.

The effects on growth were most pronounced in the very early stages of development.

Auxin-assays by means of the Avena-coleoptile method showed that the auxin content of dry seeds of the two varieties was essentially the same but that after the experimental treatment Kafir seeds contained considerably more hormone than Milo. Before and after soaking, the relative hormone concentrations (not total contents) in Milo seeds were about 75 and 45 per cent, respectively, of those in Kafir seeds. Three factors may be involved—i.e., rate of auxin formation, permeability of seed coats to the hormone, and distribution of the hormone between the endosperm and the embryo. The available evidence indicates that Dawn Kafir seeds are much less permeable to auxins than Yellow Milo seeds.

The experiments also showed that unmutilated, auxin-deficient seedlings may be easily produced experimentally. Such seedlings may be useful agents in investigations of the physiological rôle of auxins in plant cells.

# THE EFFECT OF BORON IN THE SUBSTRATE ON CALCIUM ACCUMULATION BY SOYBEAN PLANTS <sup>1</sup>

C. E. Minarik and J. W. Shive

THE FIRST INVESTIGATORS to suggest an association between boron and calcium in plant metabolism were Brenchley and Warington (1927). Later work by Warington (1934) showed that the absence of boron from the nutrient solution depressed the amount of calcium absorbed by Vicia faba as compared with controls which received boron. A report by the Department of Plant Physiology, New Jersey Agricultural Experiment Station (1937) also suggests that boron may influence the normal metabolism of calcium in plants. Analyses of plant tissues by various workers (Bobko, Syvorotkin, and Filippov, 1939; Hill and Grant, 1935; Rehm, 1937) indicate that the addition of boron to the substrate increases the calcium content of the plants as compared with check plants receiving no additional boron. Other reports (Hill and Grant, 1935; Talibli, 1935) state that boron decreases the calcium content of plants as compared with controls. Several other investigators (Holley and Dulin, 1937; Morris, 1938) have found that the presence or absence of boron in the nutrient medium has no effect on the amount of calcium in the plant tissues which were analyzed.

These inconsistent results suggest that if boron actually does influence calcium metabolism its effect varies with the species of plant investigated and with the conditions under which the experimental

procedure is carried out.

The purpose of this investigation was to determine the effective range of boron concentrations for optimum growth and to study quantitatively the effect of boron on the calcium metabolism of representatives of the two great groups of plants, monocots and dicots, whose morphological structure and physiological behavior differ widely and whose boron requirements are notably dissimilar. The plants selected are soybeans, a representative of the dicots, and corn, a representative of the monocots. The present paper deals with the results obtained with soybeans. The data obtained with corn will be presented in another publication. A preliminary quantitative investigation of the rates of calcium absorption and accumulation by the corn plant as affected by variable concentration of boron in the substrate presents a picture which bears little resemblance to that obtained for soybeans described in the following pages.

EXPERIMENTAL METHODS.—For these experiments sand culture was employed. The sand used had been previously treated with five per cent hydrochloric acid and thoroughly washed. This was followed in the same manner with a five per cent solution of ammonium hydroxide in order to remove any substances which might furnish boron or any other nutrients to plants growing in the sand. This precau-

<sup>1</sup> Received for publication August 29, 1939.

Journal Series paper of the New Jersey Agricultural Experiment Station, Department of Plant Physiology.

tion is necessary since boron from unknown sources present in the experimental set-up would render the results obtained from such cultures of doubtful value. Sand subjected to the above treatment was tested and found to be inert as far as plant nutrients are concerned.

Seeds of the Harbinsoy variety were obtained from the Agronomy Department of the New Jersey Agricultural Experiment Station. They were selected for uniformity of size and shape, soaked in tap water for several minutes, and then transferred to moist blotters. When the seeds had germinated and the tap roots were about five centimeters long, uniform seedlings were transferred to nine inch glazed pots which were filled with sand previously treated as described. The glaze on the pots employed was free from boron as determined by test. Three plants were placed in each pot. Solution was applied to the surface of the sand by the continuous solution renewal method of Shive and Stahl (1927).

A four salt standard solution prepared with sodium nitrate, calcium chloride, primary potassium phosphate, and magnesium sulfate previously used and tested by Shive (1936) in boron studies was here employed. Iron and manganese were added at the rate of 1.0 ppm. and 0.5 ppm., respectively. Boron was added at fourteen different concentration levels varying from 0.0 ppm. to 10 ppm. Duplicate

cultures were grown.

In eighteen days boron toxicity symptoms appeared in the leaves of the plants receiving 10 ppm. of boron. Necrotic spots also appeared on the leaves of the plants receiving low concentrations of boron. In the latter case, however, the spotting was due to iron toxicity, for when iron was withheld from the plants with spotted leaves the new leaves that were produced were normal. Iron was withheld for twelve days. When iron treatment was resumed, it was added at the rate of 0.25 ppm. to all cultures. Manganese was reduced from 0.5 ppm. to 0.25 ppm. since the reduced amount was found to be just as effective for the growth of soybeans as was the higher concentration. The plants were grown for seventyeight days before being harvested. At this time they had produced seed pods but the pods were not mature. At harvest the plants were fractionated into leaf blades, stems and petioles and seed pods. The fractions from the three plants in each culture were combined and weighed together. The tissue was then cut into small pieces, thoroughly mixed and aliquots were taken for dry weight determinations. The material was dried in an oven at 75°C. and then stored in air-tight bottles. Calcium determinations were made on this tissue.

CHEMICAL METHODS.—The official micro method of the Association of Official Agricultural Chemists (1935) with a few minor changes was used for the calcium determinations. The official method uses a

two gram sample of plant tissue ignited at a dull red heat (600°C.). Since insufficient material was available, a one gram sample was used in these studies.

The solution of the ash was made to volume in a 50 ml. volumetric flask. Five milliliter aliquots of this solution were used in each determination without previous removal of silicon dioxide. In the official method the silicon dioxide is removed just before the calcium is precipitated. Although silicon dioxide is coprecipitated with calcium oxalate, it does not interfere in the titration of the oxalate ions by permanganate ions. It is not essential, therefore, that it be removed. Coprecipitation of silicon dioxide would cause a serious error if the calcium were determined gravimetrically, but it is without effect in the procedure employed.

The remainder of the procedure used was the same as the official method, except that after centrifuging the calcium oxalate, the supernatant liquid was decanted rather than removed by suction. Tisdall (1923) has shown that decantation gives just as accurate results and is much more rapid than the suction method.

The oxalate ion was titrated with 0.01 n. KMnO<sub>4</sub> instead of the 0.02 N. solution which is recommended. This change was made in order to obtain greater accuracy. The 0.01 N. KMnO<sub>4</sub> was made up fresh each day by diluting a stock solution of 0.1 N. KMnO<sub>4</sub>. The stock solution was restandardized against sodium oxalate once a week.

EXPERIMENTAL RESULTS AND DISCUSSION.—Soybean plants receiving concentrations of boron less than 0.025 ppm. were typical low boron plants. Growth was retarded, the apical meristems died, and while axillary buds developed, they were short lived. The leaves developed necrotic spots between the veins and remained small. Plants receiving between 0.025 ppm. and 1.0 ppm. of boron appeared to be normal healthy plants. The leaves were dark green and were free from necrotic spots. Plants receiving

2.5 ppm. of boron and higher concentrations showed toxicity symptoms. The old leaves were chlorotic, and necrotic spots appeared along the margins. In the later stages of boron toxicity the necrotic spots were not confined to the leaf margins but appeared over the entire leaf surface. All the leaves, young and old, became chlorotic and spotted. The plants receiving toxic amounts of boron did not attain the full height that the normal plants did, but they were not stunted so badly as the boron deficient plants.

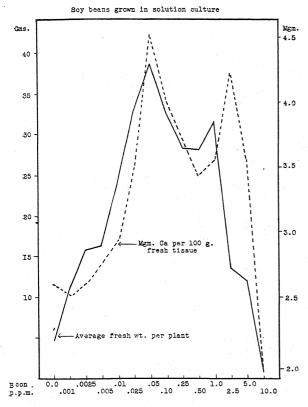

On the basis of the weight of fresh tissue produced per plant, as indicated by the data of table I, the optimum range of boron concentration for Harbinsoy soybeans grown under the conditions of these experiments lies between 0.025 ppm. and 1.0 ppm. Concentrations above and below these values were considerably less effective in the production of tissue than were the concentration in the optimum range.

Inasmuch as calcium generally accumulates to a greater extent in the leaves of a plant than in any other tissues, only the leaves were analyzed in this experiment. The calcium content of the leaf blades as well as the fresh weight per plant is roughly proportional to the amount of boron in the nutrient solution when sub-optimal quantities of boron are present in the substrate. When super-optimal quantities are present in the substrate, this relationship becomes an inverse rather than a direct one. This is clearly brought out by the comparative graphs of figure 1, in which the ordinates on the left represent the average weight of fresh leaf tissue per plant, and those on the right represent the average calcium content in milligrams per gram of fresh leaf tissue. Absissas indicate boron concentration of the substrate in parts per million.

When the concentration of boron in the nutrient solution was low enough to retard growth, the accumulation of calcium in the leaves was much lower than when optimum concentrations of boron were

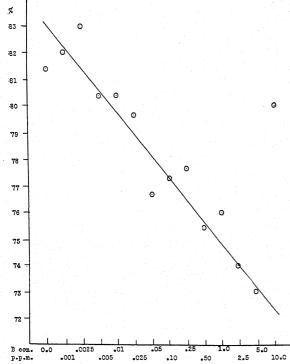

Fig. 1 (above). Graphs showing the average leaf yields and calcium content of leaf tissue in relation to boron concentration of the substrate.

Fig. 2 (below). Graph showing the effect of the boron concentration of the substrate on the moisture content of

present. When the concentration of boron was optimum for growth, the calcium content of the leaf blades was at a maximum. Concentrations which were toxic to the soybean plants reduced the amount of calcium accumulated as compared with plants receiving optimum quantities of boron. A marked deviation from this general rule occurred when the boron concentration was 2.5 ppm. Here the calcium content was quite high and the fresh weight per plant was quite low. No satisfactory explanation for this discrepancy can be made.

The graph representing the amount of fresh leaf tissue produced, as influenced by the concentration of boron in the substrate, closely parallels the graph representing the calcium content of the fresh leaf tissue. This similarity indicates a close correlation between tissue production and calcium content and shows that both are affected by boron in the same manner and to approximately the same degree. It is apparent from the data in table 1 and figure 1 that concentrations of boron above or below the optimum range produce plants with low calcium content as compared with plants in the optimum range of boron concentrations. This reduction in the calcium content below that of the plants in the optimum range may be sufficient to produce the symptoms generally associated with calcium deficiency. It is well known that the symptoms of calcium deficiency are rather similar to those produced by boron deficiency. Consequently, the symptoms of boron deficiency may be accompanied by those of calcium deficiency without easy detection. Calcium deficiency in such a case may be the indirect effect of boron deficiency, since the direct effect must be a change in the protoplasmic complex which makes it impossible for the plant to accumulate sufficient calcium for the maintenance of its normal metabolic activities.

Rehm (1937) working with Impatiens balsamina found that the addition of boron to the nutrient medium increased the intake of cations and retarded the intake of anions as compared with cultures lacking boron. Rehm suggests that boron unites with alcohols and sugars forming strongly acid compounds. This shifts the isoelectric points of the protoplasm to the acid side and favors the adsorption of cations and retards anion adsorption. This generalization is not substantiated by the work of Morris (1938), who found that the amount of calcium, potassium, and phosphorus in boron deficient oranges was no different from the amount present in normal fruit. Holley and Dulin (1937) likewise found no interrelation between boron and calcium or magnesium.

Talibli (1935) analyzed flax straw and found that the addition of boron to the substrate decreased the concentration of calcium, potassium, nitrogen, and phosphorus in the plants as compared with check plants. These results are not in line with Rehm's generalization.

The work of Rehm (1937) conclusively shows that his theory is applicable to Impatiens balsamina,

leaves. The ordinates indicate the percentage moisture and the abscissas the boron concentrations.

but apparently it does not apply to other species. The data in table 1 support the theory that calcium deficiency accompanies boron deficiency, but neither Rehm's theory nor the one presented here may be regarded as applicable to all plants.

In the case of plants receiving toxic quantities of boron the calcium content of the tissue is as low as that of plants receiving insufficient amounts of boron, yet here no symptoms which are usually associated with calcium deficiency are apparent. An explanation for this condition might be that a larger percentage of the total calcium present may be in an active form as compared with the percentage of active calcium in boron deficient plants.

Haas (1929) has shown that the calcium content of citrus and walnut leaves from plants which received toxic quantities of boron was less than the amount present in leaves from normal plants. However, the percentage of the total calcium that was water-soluble was higher in leaves of plants which received large quantities of boron than in the leaves of normal plants. Haas interpreted this to mean that the leaves showing toxicity symptoms did not mature, since the ash constituents of such leaves were present in the same proportions as they were in immature normal leaves. It may also mean that the calcium present is not precipitated and thus rendered inactive. Consequently, the small amounts which were present may have been sufficiently active to permit normal growth so far as calcium was con-

The data obtained with soybeans which are presented in table 1 agree with the results obtained by Haas with respect to the amount of calcium present in plants receiving toxic quantities of boron as compared with normal plants. The conclusion to be drawn from this is that quantities of boron which are toxic to soybean plants may prevent the normal accumulation of calcium in soybean leaves but that a large part of the accumulated calcium may remain water-soluble and may be sufficient to fulfill the requirement of the plant for this element.

Effect of boron on water content.—Besides influencing the tissue production and the calcium content of soybeans, boron also has an effect on the percentage moisture in fresh leaves. When the boron concentration of the nutrient solution was low, the water content of the soybean leaves was at a maximum. With rising concentrations of boron in the substrate the percentage moisture in the leaves decreased. The data in table 1 show this relationship. Figure 2 is a graphic representation of these data. The abscissas indicate the boron concentration of the nutrient solution, and the ordinates indicate the percentage moisture in the soybean leaves.

These results support Schmucker's (1935) hypothesis that boron exerts some control over the swelling of plasma colloids. Schmucker germinated pollen grains in sugar solutions with and without boron. Pollen grains in sugar plus boron germinated normally. Pollen in sugar solutions lacking boron burst shortly after the pollen tube emerged.

Schmucker concluded from this evidence that boron plays a rôle in the imbibition of water by the plasma colloids. In the absence of boron, imbibition of water is not regulated but continues until the cells burst. The presence of boron in the external medium appears to regulate the amount of water absorbed, perhaps through its influence upon the colloidal complex of the plant. The data of table 1 and figure 2 represent quantitative measurements which substantiate Schmucker's hypothesis. Boron, however, is not the only element whose absence from the growth medium produces a plant with a high moisture content. Calcium deficiency likewise increases the moisture content of plant tissues as compared with controls which received calcium. This fact further points to a metabolic relationship between the two elements in plant growth and offers a stronger basis for the suggestion that the absence of boron from the nutrient medium may produce calcium deficiency symptoms

CALCIUM CONTENT OF THE ASH .- The percentage of calcium in the ash of soybean leaves follows the same general trend that the fresh weight of leaves and the calcium content of the leaves follow. Although the percentage of ash expressed on the basis of dry tissue is not influenced significantly by the concentration of boron in the substrate, the percentage of calcium in the ash is much lower when concentrations of boron above or below the optimum range are used than when the optimum concentration of boron is present in the nutrient medium. This indicates that boron does not affect the percentage of ash in the dry matter but does influence the proportions in which the elements are present in the ash. When the percentage of calcium in the ash is low, the percentage of the other ash constituents is correspondingly high and vice versa.

#### SUMMARY

The production of fresh tissue by soybean plants as well as the percentage of calcium in the leaves of soybean plants is conditioned by the concentration of boron in the nutrient solution. Deficiency as well as toxicity quantities of boron in the substrate result in low yields and subnormal calcium in the tissues. The optimum range of boron concentrations in the substrate lies approximately between 0.025 ppm. and 1.0 ppm.

Within the range of concentrations here employed the percentage moisture in soybean plants decreases with increasing concentrations of boron in the nutrient solution. This supports the hypothesis that boron may be a regulator of water absorption by the plasma colloids.

The ash content of soybean leaves does not vary significantly with variations in the concentration of boron in the nutrient solution, but the calcium content of the ash is influenced by the boron content of the substrate, both excess and deficiency concentrations of boron in the substrate corresponding with low percentage values for calcium in the ash.

# THE GENUS MASSARIOVALSA 1

# Lewis E. Wehmeyer

THE GENUS Massariovalsa was described by Saccardo (1882, p. 569) as a Massariella with perithecia arranged in a valsoid manner. The two-celled brown ascospores have a gelatinous envelope, and the asci are given as paraphysate. Apparently, only two species have been described in this genus, M. sudans (B. & C.) Sacc., the type species, and M. caudata E. & E. which the writer (1933) has shown appears under two descriptions, the first being a description of Pseudovalsa (Prosthecium) bicornis (Cke.) Sacc. and the second a description of a good species, Pseudovalsa Ulmi Wehm.

Berkeley's type collection (Kew Herb., ex Berkeley Herb. No. 3866) of Sphaeria sudans is in reality closely related to the genus Melanconis. It differs from most species of Melanconis in the possession of larger spores which show a gelatinous envelope at first, in the slight development of the ectostroma, and in the conidial stage. These are all differences of degree but seem sufficient for subgeneric separation at least.

Massariovalsa sudans occurs on a number of different hosts. Berkeley's type on Acer from South Carolina and a later collection on *Ulmus* from Pennsylvania are the same as all other collections which have been examined. Ellis reports this species on Acer, Carya, and Quercus. The writer has collected it on Acer, Ulmus, and Nyssa and has received mate-

<sup>1</sup> Received for publication October 7, 1939. Papers from the Department of Botany of the University of Michigan No. 709.

rial from J. H. Miller on Acer, Nyssa, and Carya from Georgia.

Material on all these hosts is very similar (fig. 1). The perithecia are formed in small circinate groups in the upper bark cortex, have thick parenchymatic walls and cause a slight pustulate swelling of the periderm. There is very little ectostroma formed, and this is practically obliterated by the convergent emergent ostioles. The resulting appearance on the surface is a very minute black disc, consisting of the more or less fused ostioles erumpent through the center of a flat swelling, often of loosened periderm. The ascospores (fig. 6) vary in size from  $26-52 \times$ 13-18.5  $\mu$ , but there is no definite correlation between spore size and host. The spores from Acer tend to run somewhat longer than those on Ulmus and Carya, but this may be due to the larger number of collections examined on Acer. On Acer, the perithecial stage is commonly accompanied by the conidial stage. No conidial pustules have been seen on the other hosts, except those developed in culture. On Carya, the pustules are firmer, more definite, irregularly scattered, and the ectostroma is more easily seen. These differences are probably due to the character of the hickory bark, but when first seen it was taken for a Melanconis. Cultural studies have proven it to be the same as Massariovalsa sudans. The placement of this genus in the Massariaceae is undoubtedly due to the slight ectostromatic development of the disc and the gelatinous envelope found about the spores. This latter character is found in some species of *Melanconis* also, and cultural studies have shown that a definite ectostroma is formed. The paraphyses found in the young perithecium, furthermore, are broad, band-like, guttulate, and evanescent, as in *Melanconis*. The conidial stage is a modification of the Melanconium type with conidia formed within an enclosed chamber, instead of open cavities. The relationship is obviously with *Melanconis*.

In order to determine whether or not the occurrences of *M. sudans* on the various hosts represent separate species, single ascospore isolations were

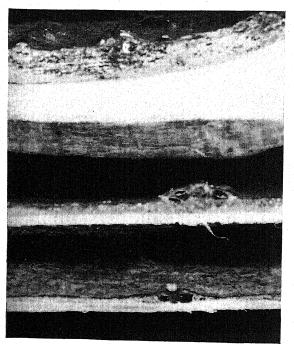

Fig. 1. Radial sections of stromata of Massariovalsa sudans (B. & C.) Sacc. on twigs of Acer saccharinum (above), Carya glabra (center) and Nyssa sylvatica (below).

made from three collections kindly sent the writer by J. H. Miller from Athens, Georgia. The hosts and dates of collection of these were as follows: Carya glabra, March 12, 1938; Acer rubrum, December 8, 1938; and Nyssa sylvatica, June 4, 1938. Certain cultural differences were observed between these host strains, but in general the results were similar. A general consideration of the strain from Carya will serve for all three strains. The varietal differences will be considered later.

Ascospores from Carya glabra were sprayed onto nutrient agar on March 26, 1938. Germinating spores were found within 24-48 hours. Only a small percentage of the spores germinated, and most of the germinating spores were cracked at the septum, with the two cells of the spore partially separated or entirely free from one another (fig. 7). Two to four, stout, gnarled, branching germ tubes,  $2.5-5~\mu$  in diameter, were put out from each spore, either from

the central ruptured septum or from the ends of the spore.

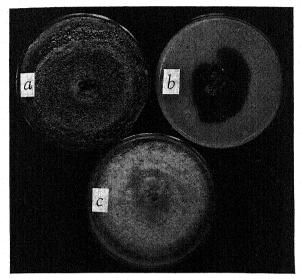

Growth was extremely slow on nutrient agar, colonies being only three to four centimeters in diameter after six months. Growth on oatmeal agar was somewhat more rapid. The surface of the agar is heavily blackened, and there is a superficial whitish to greenish-gray cottony mycelial growth. A few hemispheric stromata, of a similar greenish tint, were formed on oat agar after some six weeks. These split open, exposing a slimy inner surface. These stromata consisted of a mass of pale greenish to hyaline pseudo-parenchyma. In various internal areas, these cells put out short conidiophores which bore conidia at their apex. These conidia (fig. 8) were broadly ovoid, slightly flattened at the base where attached, hyaline at first but soon becoming olive brown and coarsely granular, finally wiith a thickened wall and homogeneous content and 26-33.5 imes 19.5-30  $\mu$ .

In the first twig inoculations the twigs dried out before fruiting occurred, because of the slow growth of the fungus. Autoclaved twigs of Carya sp. inoculated on November 2, 1938, showed numerous minute elevations of the periderm by December 29, and these later gave rise to erumpent, spheric, grayish stromata which finally showed the splitting off of a cap-like apical portion, similar to that found in agar cultures. The conidia were exuded in a black slimy mass and were identical with those found on agar.

Sections through these areas show that the pustules arose as rather widespread but interrupted areas of ectostroma on the bark surface. These ectostromata (fig. 4) are at first composed of loose, erect, hyaline, somewhat interwoven hyphae,  $2-3~\mu$  in diameter, causing a separation of the periderm from the bark cortex. These hyphae soon show a definite tendency to form a pseudo-parenchyma by the swelling and septation of the strands and the rounding up of the individual cells. This change occurs first at the base and in the central portions of these areas. As a result of subsequent increase in cell size, these central areas swell rapidly to an irregular spheric form and cause the pustulate ruptures of the periderm, and eventually the erumpent stromata.

The cells of this stroma are at first hyaline, filled with protoplasm and capable of continued growth. Upon exposure, the outer cells become thick-walled, olive-brown in color, and limit the expansion of the stroma. The inner cells remain hyaline and active, and at one or several points conidial formation is initiated. In these areas, the smaller more active cells may grow out directly as conidiophores, but the larger parenchymatic cells "sprout" by the rupture of the thin hyaline wall and the outgrowth of the naked protoplast as a conidiophore (fig. 9). The conidiophores are short, stout, 7-18  $\times$  2-4  $\mu$ , and often tapered to a point at the apex. The ruptured wall of the mother cell often appears as a sheath at the base. The conidiophores swell at the apex to form the ovoid conidium which is hyaline until it reaches nearly full size, when the wall becomes

thickened and a dark olive-brown. The conidia are  $21.5-27 \times 17.5-22~\mu$ . The formation of conidia continues centrifugally until one or a few large cavities result, limited by the outer wall of inert cells. The

pressure resulting from spore production causes a rupture of the stroma, which usually takes place by the throwing back of a lid-like slice of the upper portion of the stroma.

Variations from the above life history are indicated in the following comparison of the three host

strains. Inoculations of the three strains were made in triplicate on oatmeal agar, and two series were carried for three weeks each. Certain definite differences appeared and were constant for each strain. These are described below and illustrated in figure 2.

On Carya: Colonies 2-4 cm. in diameter (after 3 weeks). Young colony with fine superficial tomentum which is grayish when viewed at a wide angle to the light. Soon forming a heavy dark green-black growth in the agar, giving the entire colony this color. Later a fine cottony growth of grayish mycelium may occur on the blackened stromatic areas. No pycnidia after three weeks.

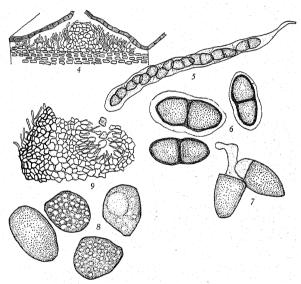

Fig. 4-9. Massariovalsa sudans (B. & C.) Sacc.—Fig. 4. Vertical section of young ectostroma, showing development of central plug of pseudoparenchyma.—Fig. 5. Ascus.—Fig. 6. Ascospores.—Fig. 7. Germinating ascospores.—Fig. 8. Conidia as formed in culture.—Fig. 9. Section of conidial locule and wall as formed in culture.

On Acer: Colonies 3-7 cm. in diameter. General color of the colony yellow-brown. Growth in concentric fan-like waves forming an outer tufted, superficial, yellow-gray mycelium behind which there is a more appressed superficial growth of darker yellow-brown hyphae arranged in a radiating system of very fine, loosely floccose, mycelial strands. Numerous grayish, superficial, spheric stromata, 0.5-1.0 mm. in diameter, with amber colored droplets present.

On Nyssa: Colonies 7-8.5 cm. in diameter. Surface growth of flocculent white mycelium, continuous or zonate in some colonies, 0.1-0.2 mm. thick. Agar with a characteristic tan to red-brown discoloration. Numerous minute, greenish-black stromata within the agar, which later proved to be perithecia.

On March 26, 1939, each of the strains from Acer, Carya, and Nyssa were inoculated onto three twigs each of Acer, Carya, and Ulmus (Nyssa twigs not being available). Figure 3 shows one set from this

series after eight weeks' growth. The growth of any one strain on the three hosts was very similar. There was somewhat greater superficial mycelial growth in the case of the Carya strain, but this may have varied with air moisture. The lack of growth of the Acer strain on Carya, for instance, was due to the drying out of the twig. The more important differences are cited below.

The Nyssa strain failed to produce any conidial stage in any of the many cultures carried, either on agar or on twigs. On the other hand, perithecia were produced in all these cultures but in none of the cultures from the other hosts. The perithecia formed were small and abnormally developed, but typical mature two-celled, brown ascospores were found in many of them.

The pycnidia formed by the strain from Acer did not open by the cap-like splitting of the apex, as is common in the Carya strain. The conidia of the Acer strain were exuded through a pore-like opening as fine coiled tendrils, rather than shapeless spore masses. The conidia of the Acer strain on twigs of Acer  $(23-32\times19.5-23\,\mu)$  and Ulmus  $(26.5-32\times18-21.5\,\mu)$  were slightly narrower and more ovoid than those of the Carya strain  $(26.5-33.5\times21-25\,\mu$  on Acer and  $26.5-39\times23-30\,\mu$  on Ulmus), but on twigs of Carya, both strains produced similar conidia  $(26.5-33.5\times21-25\,\mu$  for Acer strain and  $25-33.5\times21-26.5\,\mu$  for Carya strain).

These differences between the strains from different host genera are largely ones of physiological behavior, rather than of morphology and are, therefore, considered to be of varietal rather than of specific rank.

The conidial stage, obtained both in nature and in culture, is a Melanconiopsis. Ellis (1900) in describing this genus says "doubtless a stylosporous stage of a Melanconis or a Massariovalsa," and his type collection (N. Y. Bot. Gard., Ellis Coll., Kans., 1900, Bartholomew 2519) of Melanconiopsis inqui-

nans E. & E. on Acer dasycarpum is identical with the conidial stage obtained from the strain on Acer, showing the similar, somewhat narrower, conidia,  $25-35 \times 14-18 \mu$ .

This form genus can be considered as a modified Melanconium with enclosed locules. The differences between Massariovalsa and Melanconis might be considered of generic rank, but inasmuch as the genus Melanconis, as now circumscribed, has species with various affinities and variable conidial stages, the writer would prefer to place Massariovalsa as a sub-genus of Melanconis. These arrangements within the genus Melanconis will be considered in a forthcoming paper.

#### SUMMARY

Cultural studies of three strains of the one good species of Massariovalsa, M. sudans (B. & C.) Sacc., from Acer, Carya, and Nyssa, indicate certain differences considered to be of varietal rank.

The strains from Acer and Carya produced a conidial stage, identical with Melanconiopsis inquinans E. & E. The strain from Nyssa produced no conidia but numerous perithecia in all cultures.

The genus Massariovalsa is considered as a subgenus of Melanconis.

# HYDROGEN-ION CONCENTRATION OF LEAF JUICE IN RELATION TO ENVIRONMENT AND PLANT SPECIES <sup>1</sup>

# Annie M. Hurd-Karrer

THE DATA reported in the present paper show the extent to which the acidity of the wheat plant is subject to change by the environment. Hundreds of pH determinations for plants in all stages of development, grown under different environmental conditions over a period of years, are summarized in the form of distribution curves that permit determination of the most typical value and the range of variation. Some of the data are tabulated to illustrate specific effects of growth factors.

Comparative acidities of other kinds of plants are shown by a compilation of pH values reported by other investigators.

<sup>1</sup> Received for publication October 23, 1939. Numbers in parentheses refer to Literature Cited at end of this article. The significance of acidity measurements on the expressed juice of plants is enhanced by Chibnall and Grover's conclusion (7) that since the buffering power of the vacuole fluid is greater than that of the cytoplasm the hydrogen-ion concentration of the expressed juice is a close approximation to that of the vacuole fluid in the living cell.

METHODS AND MATERIAL.—The plant material was macerated by grinding in a food grinder, or in a Nixtamal mill, and the juice expressed by squeezing it out by hand through muslin or cheesecloth. It was found that preliminary freezing of the plants had little effect on the hydrogen-ion concentration of the expressed juice. The use of high pressure has been advocated; but the writer found that values for

juice expressed by hand from a thoroughly macerated pulp did not differ from those of juice expressed by pressure up to 2,000 pounds per square inch (table 1). Small differences in concentration can have no appreciable effect on the pH value of a juice as highly buffered as that of wheat (20). Hence the simpler method, which facilitated the work without seeming to introduce detectable errors, was used throughout.

Table 1. pH values of four successive expressions, with increasing pressure, of juice from eight different lots of wheat leaves.

<sup>&</sup>lt;sup>a</sup> Juice squeezed from ground tissues by hand through cheesecloth.

The hydrogen-ion measurements were made electrometrically with the hydrogen electrode and saturated calomel cell. Most of the measurements were made at a temperature of 25°C. When there was any departure from this temperature, the proper corrections were made in the calculations. The equipment and details of the method have been described previously (20). Frequent checking with M/20 potassium acid phthalate showed the system to be accurate to within  $\pm .01$  pH.

Wheat plants were grown in a fertile soil (composted Keyport clay loam) having a reaction near pH 7.0. Unless otherwise specified the measurements are for the juice of green leaves, dead or yellowish ones having been discarded. To avoid complications from environmental conditions other than the one under consideration, the plants of a given experiment were always cut at as near the same time as possible, usually in the morning.

EXPERIMENTATION.—Effects of temperature.—
The data recorded in table 2² indicate that the acidity of wheat varies directly with the temperature at which the plants are grown—i.e., the warmer the greenhouse the lower were the pH values obtained for the juice. All three varieties included in the experiment grew best at the lowest temperature, but they differed with respect to severity of injury sustained at the higher temperatures. Turkey, a winter variety, grew poorly and remained vegetative at temperatures above 20°C., while Hard Federation, a spring variety, grew fairly well at temperatures as high as 20° to 25°, but poorly at 25° to 30°. Table 2 shows that Turkey became much more acid at temperatures above 20° than did Hard Federation. Harvest Queen was intermediate between the

<sup>2</sup> This table is a rearrangement of data published previously (25) plus some additional measurements for the same lots of plants after the period of temperature control (i.e., after 18 weeks).

with respect to both temperature requirement and acidity. Therefore it is concluded that the degree of acidification produced by high temperature is determined by the susceptibility of the variety to high-temperature injury. No varietal differences were found in any experiment where temperatures were low enough for equally vigorous growth and development of all the plants.

- d No heads; plants severely injured.

Effects of day length.—Table 3 gives data obtained with Turkey, a winter wheat, showing that the pH value varied inversely with length of the daily period of light. Decreasing the light period from the natural day to 8 hours, by methods described previously (27), produced vegetative, unfruitful plants with consistently higher pH values than those of adjacent control plants with a normal day of 9 to 15 hours; and lengthening the light period to 17 hours by means of artificial illumination produced stunted, prematurely ripening plants with pH values generally lower than those of the controls.

In some later experiments with a spring variety (cf. table 6) shortening the light period to 8 hours had no effect on the measurements, although length-

ening it to 17 hours increased the acidity in two out of three experiments.

Effects of late sowing.—Wheat sown too late in the season for normal development is characterized by abnormally high acidity, especially spring-sown winter wheat whose heading is inhibited. Table 4 shows the increasing acidity of poorly developing plants of both a spring (Jenkin) and a winter (White Odessa) variety sown in a greenhouse at Arlington, Virginia, in March, compared with corresponding measurements on vigorous plants of January sowings. Tables 2 and 3 show that both high temperature and long days are factors in the late spring environment that tend to bring about this acid condition.

Newton et al. (42) give data that show such an effect of late sowing on the acidity of the winter variety, Kanred. Spring varieties sown at the same time maintained a normally low acidity, with pH values between 5.91 and 6.35, over a period during which the acidity of Kanred increased to pH 5.64. Kanred is described as having "behaved in the usual manner of a winter wheat seeded in the spring, failing to joint or progress toward maturity." In a later paper (41) Newton and Brown report abnormal

acidities increasing from pH 5.60 to 4.87 over a period of six weeks in young plants of very late (June 9) sowings of Kanred.

Effects of light intensity.—The considerable difference in intensity of the artificial light supplied from sunset to midnight to two different lots (A and B) of long-day wheat (table 3) had no effect on the pH value. Significantly, there was no detectable difference in the appearance nor rate of development of the plants.

Many plants, especially fleshy or succulent ones (29), show pronounced diurnal changes in acidity, but those of wheat are small. Series of measurements on wheat for the entire 24-hour period are given by Loehwing (33). They show that the pH value is at a minimum in the early morning and at a maximum in the evening. Differences between morning and afternoon cuttings similar to those of Loehwing have also been reported by the writer (20).

Effects of etiolation.—The acidity of juice from etiolated wheat seedlings grown for a week to 10 days in the dark (in unlighted germinators at temperatures near 20°C.) averaged a little higher than that for green seedlings. The difference is shown by the data of table 5 and by another group discussed later in connection with frequency distributions (fig. 1). However, differences were small, and the ranges overlapped. Moreover, the probability of variation in other factors of the germinator and greenhouse environments, such as temperature and humidity, preclude attributing the acidity differences to etiolation alone with any degree of certainty. More significant than their difference is their similarity, indicative of effective functioning of the buffer system before initiation of photosynthetic processes. There is evidence (26) that inorganic phosphates are the

buffers largely responsible for regulating the hydrogen-ion concentration of such plants as wheat.

Effects of soil reaction.—In order to determine whether liming the soil affects the acidity of wheat, calcium hydroxide was added at a rate of four tons per acre to composted Keyport clay loam. The limed and unlimed soils were in the same greenhouse bench but separated by a buffer compartment containing dry soil. The pH values for 1:1 water extracts were

6.95 to 7.28 for the unlimed soil and 8.01 to 8.18 for the limed soil.

The data of table 6 show that the acidity of the wheat juice was not decreased by the lime. In the experiment of table 3, also, there was no appreciable difference between values for plants from limed and unlimed soils. In both of these experiments, vigor of growth was not affected by the lime. In some earlier experiments (20) it had reduced the juice acidity by as much as 0.2 pH, interpreted as an indirect result of the favorable effect of lime on growth in the particular soil used.

Limits of variation and the range for normal plants.—The pH values for wheat reported in this and previous papers (20, 22, 23, 25), together with other unpublished data, are assembled in the frequency distribution curves of figure 1.

The largest group, that of curve no. 1, comprises all the data—i.e., pH values for 707 different samples of juice from green plants of all ages and en-

vironments. They range from pH 5.31 to 6.38, with 80 per cent of them falling between 5.81 and 6.20. The frequency distribution curve is not normal but unsymmetrical because of extension on the left, in the direction of values more acid than the mean. Obviously this form results from inclusion of a relatively small number of plants more acid than most of the material of the experiments. These more acid plants are (1) the older ones, in the maturation

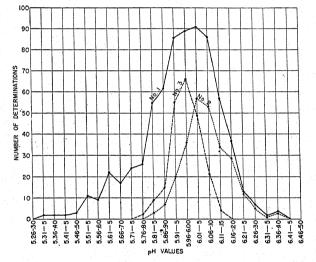

Fig. 1. Frequency distributions of pH values for three groups of wheat plants: No. 1, green plants irrespective of age or condition; No. 2, the same group after elimination of data for plants older than 12 weeks and for unhealthy plants; No. 3, week-old seedlings grown without light.

period, and (2) those in an abnormal or unhealthy condition from any cause, such as late spring sowing, unfavorably high temperatures, or artificially lengthened light periods.

When the data for the older and the unhealthy plants are omitted from curve no. 1 (specifically, values for plants beyond the tillering stage, or older than 12 weeks, and for plots sown later than March 1, or in greenhouses where temperatures were above 20°C. or where light periods were other than the normal day length) frequency curve no. 2 (of figure 1) is obtained. The 260 values range from 5.85 to 6.38 about a mean at pH 6.07. Their distribution conforms so closely to a normal curve calculated from the data (fig. 2) as to permit the inference that the deviations from the mean are only those to be expected as random variations of an essentially homo-

geneous population.<sup>3</sup> Such homogeneity was unexpected, because no attempt had been made to produce identical environments for the several different years' experiments that supplied the data. Evidently the variables in the environment that remained after the eliminations noted had little effect on the plant

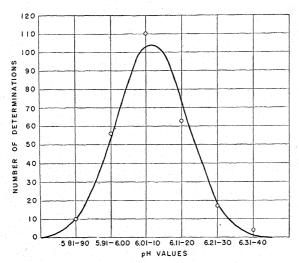

Fig. 2. Normal distribution curve calculated from pH values of juice from healthy vigorous wheat plants not more than 12 weeks old. (Calculations made and curve drawn by O. E. Rauchschwalbe of the Division of Cereal Crops and Diseases, Bureau of Plant Industry.)

acidity. It can be concluded that the range pH 5.9 to 6.2, within which 88 per cent of the values fall, represents the most usual acidity of wheat in the vegetative stage.

During the maturation period, beginning usually some time before flowering, there is a progressive increase in acidity (22, 24), sometimes to pH values as low as 5.3 (tables 2 and 3). Other data showing this trend have been published by Newton and Brown (41) for wheat, Haas (14) for buckwheat, Miyake and Adachi (37) for oats and flax, May (36) for tomato, Górski and Dabrowska (13) for legumes, and Garner et al. (12) for tobacco.

It is of interest to note the narrow range of variation in pH values obtained for etiolated wheat seedlings of 23 different varieties grown for a week to 10 days in unlighted germinators with temperature controlled automatically at about 20°C. The range for the 221 values, whose distribution is shown in curve no. 3 of figure 1, was from 5.80 to 6.14, with 86 per cent between 5.91 and 6.10, and conforming, as shown by the chi-square test, to a normal distribution about a mean at pH 5.97.3 The somewhat narrower range of values as compared with the corresponding range for the green plants presumably reflects the greater constancy of the environment in the germinators as compared with that in the greenhouse.

<sup>3</sup> It is recognized that such interpretations of statistical treatments of pH values—i.e., of negative logarithms—may be open to question.

PH VALUES REPORTED FOR OTHER CROP PLANTS.—
Hydrogen-ion determinations reported in the literature for other crop plants are summarized in table 7. The compilation has been limited with few exceptions to electrometric measurements on the juice of leaves, or occasionally of whole tops, of plants subjected to normal growth conditions. Sometimes, however, the exact tissues used were not specified by the investigator. Sometimes the range of values given is inclusive for varying conditions produced for the particular investigation, such as different hours of sampling and different soil conditions. It is therefore impossible to assure strict comparability of the figures, especially since differences in age and vigor will also have affected them.

The data of table 7 show that the juice of many crop plants is generally, like that of wheat, near pH 6.0. Distinctly more acid than this, but above pH 5.0, are buckwheat, corn, cowpea, the sorghums, apparently Sudan grass and sugar cane, and apparently some of the lupines and crucifers. Most acid of all are rhubarb and apparently onion. The lowest acidities, occasionally above pH 7.0, have been reported for hemp, pumpkin, squash, sunflower, sweet clover, and field pea.

It is interesting to note that the Gramineae in the list, comprising two distinct types morphologically, comprise two corresponding groups from the standpoint of acidity. These are (1) the small grains—barley, oats, rye, and wheat, with pH values near 6.0 on the average; and (2) a more acid group comprising corn, sorghums, Sudan grass, and sugar cane, with pH values generally near 5.5.

Measurements for some highly acid tissues are summarized in table 8 for comparison with the crop plants. The extremely high concentrations of acid indicated by some of the figures are undoubtedly localized in special cells or vacuoles, hence not in contact with the protoplasm, nor with the enzymes that are inactivated by such acidities (28).

Discussion.—Evidently in plant as in animal tissues (31, 38, 46) various types of injury are associated with acidification. Several investigators (15, 16, 20, 45, 47, 49, 51, 52) have found that diseased plants are more acid than corresponding healthy ones. That the pH values of wheat and corn vary with vigor has been reported previously (20, 21, 22) and a similar correlation appears in the work of Newton et al. (41, 42) where Kanred wheat, unable to develop normally because of late sowing, became abnormally acid. Also Loehwing (33) reports a lower acidity for vigorous wheat in a fertile (unlimed) soil than for less vigorous plants in a nonfertile soil. Haas (14) found that the second year's growth of alfalfa was not as acid as the less vigorous first year's growth; Dustman (10) that in some tomato seedlings grown with different quantities of calcium in the nutrient solution the acidity of the sap decreased with increasing vigor of growth; Eckerson (11) that phosphate-deficient tomato plants are abnormally acid, being essentially nitrogen-starved even though grown with an adequate

Table 7. Compilation of pH values reported by other investigators for juice of leaves of crop plants.<sup>a</sup> (References are to pages where the cited values occur.)

<sup>f</sup> The names Sorghum saccharatum and Andropogon sorghum also used.

nitrate supply; and Nightingale et al. (43) that acidity is usually higher in calcium-deficient plants than in more vigorously growing plants with adequate calcium. Truog and Meacham (50) refer to the fact that with the development of hyperacidity there is slow growth and a weakened condition, "as is the case with plants of high lime requirement growing on acid soils." Hoagland and Martin (19) raise a question as to whether any considerable modification in the normal reaction occurs except when accompanied by definite injury to the plant. One then wonders whether abnormal acidity causes the injury or whether injury, by changing the normal course of metabolism, causes hyperacidity.

Incidentally it is of interest to note that the quantity of certain nitrogen compounds in plant tissues, known to be directly correlated with succulence and

vigorous vegetative development (1, 32, 39, 44), is inversely correlated with the hydrogen-ion concentration (9, 35, 44). In agreement with the latter reports, the writer found that in an experiment with young wheat plants the correlation coefficient for the nitrogen and pH values was + 0.74  $\pm$  .10; in another with older plants it was + 0.66  $\pm$  .08.

Evidently under some conditions lime decreases sap acidity, and under others it does not. Górski and Dabrowska (13) have concluded from water culture experiments that the reaction of the plant sap depends on that of the nutrient solution; but Arrhenius (2) found the pH value to be similar for tissues of wheat plants grown in nutrient solutions ranging from pH 3 to 10; Keyssner (30) found it almost the same for leaves of wheat and other plants in solutions of pH 3.8 to 7.6; and Hoagland (17) found

Table 8. pH values for the expressed juice of some highly acid tissues.

that it remained quite constant in barley in spite of wide variations in the reaction of the solutions. Hoagland and Davis (18) found that the pH value for Nitella cells was approximately constant at 5.2 in solutions ranging from pH 5 to 9. Theron (48) also reported that the reaction of juice expressed from the tops of plants is not directly influenced by the reaction of the culture medium. Nightingale et al. (43) found acidity to be increased usually by calcium deficiency, but Newton (40) and Dustman (10) found no appreciable increase. Truog and Meacham (50), Bauer and Haas (4) and Haas (14) found that the acidity of most of their crops was decreased by liming the soils, although a few were not. Truog and Meacham noted that one of the exceptions was the blue lupine which was sometimes injured by liming; hence they raise the question as to whether or not injury may result in an increase in acidity.

The large effect of lime on the reaction of the juice of wheat grown by Loehwing (33) on an acid humus soil, where it was in poor condition, is significant in this connection. Loehwing points out that the mineral nutrition of the plants was inadequate. Their pH values, often as low as 5.5, would in themselves indicate abnormality, according to the results of the present investigations. As Loehwing recognized, the great reduction in this acidity when the soil was limed, often to about pH 6.5, reflects a low buffer capacity resulting from inadequate mineral nutrition. Significantly, these limed plants, unlike those of the present investigation, eventually became chlorotic and unhealthy, and their acidity then increased. Loehwing concludes therefore that the extremes of high and low soil acidity may both result in hyperacidity of the sap. Clevenger (8) and Bystrikov (6) also report instances of sap acidity increased by lime.

It thus seems likely that the contradictory results reported in the literature on the effect of the reaction of the substratum on that of the plant sap may be explained on the basis of particular effects on growth. For example, wheat will not make its best growth at soil acidities greater than that indicated by a pH value of 6.0 (3, 5, 34); so liming soils more

<sup>4</sup> Optimum growth of wheat in nutrient solutions more acid than pH 6.0 has been reported, but such results may be due to reduced growth from iron deficiency in the less acid solutions (29).

acid than pH 6.0 can be expected to improve the condition of wheat and decrease its acidity, unless chlorosis or other injury occurs. But when the soil reaction is optimum for a given crop, and mineral nutrition adequate, and if vigor is not affected by change in other soil conditions, apparently no effect of lime on sap acidity is to be expected.

#### SUMMARY

pH values of the expressed juice of leaves of normal, vigorous wheat plants during the vegetative period ranged from 5.85 to 6.38 but were usually between 5.9 and 6.2. During the maturation period acidity increased, the pH value generally falling to about 5.5, rarely as low as 5.3.

Unhealthy plants became prematurely acid, but none reached pH values lower than 5.3.

Both high temperatures (above 20°C.) and lengthened daily light periods (17 hours) tended to increase acidity under experimental conditions, accounting for the abnormal acidity of spring-sown winter wheat, which grows poorly and fails to head.

The extent to which high temperature increased acidity depended on the extent to which it injured the plants. Thus acidity at the higher temperatures was determined by the temperature requirement of the particular variety.

There was no significant varietal difference in the pH values for plants grown under conditions equally favorable for normal development.

The only environmental factor found to reduce acidity was a shortened daily light period (8 hours) which favored vigorous vegetative development.

pH values for week-old seedlings grown in the dark averaged slightly lower than those for seedlings grown in the light, but the small differences are of doubtful significance.

Liming the soil had no effect on the juice acidity in these experiments, presumably because there was no effect on vigor of growth.

A compilation of reports from the literature for other plants shows a range from near pH 1 for Begonia, to near pH 7 for occasional samples of the least acid crops, with the majority between pH 5.5 and 6.5.

# THE EFFECTS OF MAGNESIUM AND CALCIUM ON "WHITE TIP" OF RICE 1

# Alan L. Martin

A PHYSIOLOGICAL disorder known as "white tip" is frequently observed in field rice during the midseason and late growing periods. Mild forms of this disease are characterized by the appearance of white chlorotic areas at the tips of one or more of the new leaves of the plants. In more advanced stages the chlorotic area moves down the leaf, usually involving about half the structure, and a half inch or more of the leaf tip dies and dries up. When the flag leaf is injured, the panicle sheath remains very tightly rolled so that the head is compressed as it emerges from the boot. The sheath is frequently so tightly twisted that the head has to force its way through the side in order to emerge. The few flowers which are borne on heads that emerge in this manner are often sterile or produce distorted grains, resulting in decreased yields.

The similarity between these symptoms and the chlorosis described for magnesium deficiency in oats, wheat, and tobacco (Dickson, 1918; Hartman and Powers, 1928; Moser, 1933; Garner et al., 1930) led to the investigation of the effects of various magnesium concentrations on rice. It was hoped to determine whether magnesium deficiency would produce a condition similar to the disease known as white tip, whether the addition of magnesium to the growing medium would correct this condition, and whether there was an optimum magnesium:calcium ratio. Interest in the study of the effects of calcium on rice was increased by the common belief among growers that lime is detrimental to the crop.

Soil cultures in the greenhouse.—Methods and experiments.—Dark phase Crowley clay, which had produced a large percentage of white tip the previous year, was obtained at the Beaumont Rice Experiment Station. The soil was air dried for two weeks, being mixed and turned repeatedly. Eight kilograms of dry soil were placed in each of the 3-gallon glazed stoneware crocks used as culture vessels. Crocks of soil to which neither magnesium nor calcium had been added were used as controls. Magnesium, as magnesium chloride (Mg Cl<sub>2</sub> · 6H<sub>2</sub>O), was supplied in solution to a series of cultures in concentrations of 3, 9, 27, 81, 243, and 486 ppm. A like series using calcium, as calcium chloride (Ca Cl<sub>2</sub>), was set up. In the remaining series these quan-

tities of the two salts were arranged so as to give magnesium:calcium ratios ranging from 1:1 to 1:81 and calcium:magnesium ratios in a range between 1:1 and 1:162. All concentrations were calculated on the basis of the dry weight of the soil, and the solutions were allowed to dry in the soil before planting. Ten rice seeds of the Early Prolific variety were planted in each crock, and the soil was kept damp. The crocks were placed on tables in the greenhouse and their relative positions changed weekly. When the seedlings were about five inches high, all but the five healthiest plants were removed, and a 2-inch flood of water was put over the soil. This depth of water was maintained until harvesting, with the exception of one 5-day "dry-up" to eliminate premature yellowing of the leaves. The cultures were run for a period of 18 weeks, and dry weights of the straw and of the seeds were obtained after harvesting.

Results.—The soil used in these experiments had previously produced severe white tip injury on rice plants in the field; when used in crocks in the greenhouse, white tip occurred on 40 per cent of the plants. Incipient injury appeared after ten weeks as a chlorotic white spot just below the dry brown tips of the young third, fourth, or fifth leaf. This condition spread downward until the entire leaf dried up. Before the emergence of the panicle the sheath often remained tightly rolled, and the flag leaf was stunted, thus showing severe white tip injury. The panicle was unable to emerge normally, and many flowers were injured or failed to develop; this resulted in a decreased yield of mature seeds. The plants affected by white tip were not so sturdy nor so tall as the others in the same culture. When magnesium was added to the soil cultures in concentrations of 3, 9, 27, 81, 243, and 486 ppm., the foliage of all plants was a dark green. Examples of white tip occurred when less than 81 ppm. of magnesium were used. The addition of calcium to the soil cultures in concentrations of 3, 9, 27, 81, and 243 ppm. did not produce much change in the appearance of the plants. The plants affected with white tip were light green in color, and they were all of about the same height in the different cultures. The dry weights revealed that increases in calcium supply produced corresponding increases in straw but had slight effect on seed production. When 486 ppm. of calcium was

added to the soil, the culture became slightly toxic as was shown by a decreased growth rate.

White tip occurred on the lower leaves of about 20 per cent of the plants when 3 ppm. of magnesium, with various concentrations of calcium, were added to the soil. This condition was an improvement over the cultures to which magnesium alone had been added, but there was no magnesium:calcium ratio which was distinctly beneficial with this small amount of magnesium. The addition of 9 ppm. of magnesium with varying quantities of calcium produced a greater reduction in the number of white tip leaves; however, this result depended more on the increased magnesium content than on the concentration of calcium. When 27 ppm. of magnesium and the various concentrations of calcium were added to the soil, only 4 per cent of the plants had white

tip, and in this series there were three cultures which were completely free from this symptom. Cultures supplied with 27 ppm. of magnesium and to which 27, 81, and 243 ppm. of calcium were added produced no white tip. When 81 ppm. of magnesium were added, white tip was eliminated regardless of

the calcium content. When both magnesium and calcium were added to the soil in concentrations of 3, 9, 27, and 81 ppm., the height of the plants was not greatly affected by the different quantities. Figure 1 shows a trend for 3, 9, and 27 ppm. of magnesium with the lower concentrations of calcium to increase the dry weights of seeds. Figure 2 shows that the addition of 3, 9, and 27 ppm. of calcium to non-toxic quantities of magnesium tended to increase the dry weight of straw and for 3 and 9 ppm. of calcium to increase the dry weight of seeds. All cultures to

which 243 ppm. of magnesium were added were free from white tip, but they showed effects of magnesium toxicity. Early death of one or more plants occurred in each culture regardless of the calcium concentration, and no seeds had ripened by harvest time. Magnesium in 486 ppm. concentration caused death to all plants before the tenth week, and the addition of calcium hastened death.

Discussion.—The addition of magnesium chloride to soil which had previously produced white tip caused the plants to grow normally. The use of low

concentrations of magnesium reduced the number of cases of white tip, and the addition of 81 ppm. of this element completely eliminated the injury. The application of 243 ppm. of magnesium was toxic and 486 ppm. was lethal. Plants grown in this soil were uniformly light green in color unless a sufficient quantity of magnesium was present. Since magnesium is one of the constituents of chlorophyll, its absence may induce this chlorosis (Willstatter, 1909; Mameli, 1915). The characteristics of the white-tip condition lead to the assumption that it is closely related to the assimilation of chlorophyll forming ele-

ments. When the flag leaf was affected, seed vield was decreased. This may have resulted from the reduction of photosynthetic tissue during panicle formation as well as injury to the head by the pressure of the tightly whorled boot. Plants severely affected with white tip become stunted, although they reach maturity. When magnesium deficiency is overcome. the general tendency is to increase the yield of seed. Dickson (1918) reported similar results with oats. The addition of calcium salts in concentrations as great as 243 ppm. had no noticeable effect on the white-tip condition. Calcium in concentrations of 3. 9, and 27 ppm. had a tendency to increase straw production. None of the magnesium calcium ratios employed in these experiments could be considered to show optimum growth, regardless of concentration. This corresponds to the conclusions drawn by Lipman (1916) and Moser (1933). Although there were several cases in which magnesium injury was reduced by the addition of calcium to the soil cultures, these were not consistent or of sufficient degree to show clear evidence of antagonistic action.

Solution culture experiments.—In order to control nutrient conditions more effectively, water culture experiments were run in the greenhouse. It was hoped that if the magnesium:calcium ratio could be more accurately controlled the antagonistic effects of the two elements would be more pronounced.

Methods and experiments.—Rice seeds of the same stock as that used in the soil experiments were hulled by rolling on a rubbing board with a pigskin covered block. The seeds were then sterilized by soaking for five minutes in a 1:1000 solution of bichloride of mercury. Following a thorough washing to remove the disinfectant, they were placed in distilled water and kept in an incubator at 35°C. for 96 hours. At the end of this period, practically all the embryos had roots from 5 to 7 mm. long and coleoptiles about 2 mm. in length. Selected seedlings of a uniform size were placed root downward on paraffined bobbinet stretched over enamelware pans filled with distilled water and were allowed to grow in the greenhouse for eight days.

The culture vessels were 2-quart Mason jars covered with brown wrapping paper to shield the roots from the light. Each jar was fitted with a paraffined cork stopper having four holes to accommodate the plants. Young plants 7 cm. tall were placed in the corks and held in position with small tufts of cotton. The relative positions of the cultures were changed weekly.

The basic nutrient solution contained the following salts: ammonium nitrate, 0.001 M; potassium dihydrogen phosphate, 0.001 M; sodium sulfate, 0.001 M. Iron (as ferric nitrate in citric acid solution) was added weekly in sufficient amounts to maintain a concentration of 0.00001 M in the solution. The minor elements were supplied in the concentrations suggested by Trelease and Trelease (1935). The magnesium and calcium concentrations and ratios were the same as those used in the soil-

culture experiments. The solutions were prepared with water from a tin-lined still, and the solution level in each culture vessel was kept nearly constant by adding distilled water every other day. The reaction of each solution was adjusted to pH 6.5 by adding sodium hydroxide, and all solutions were renewed during the fifth week. The height and dry weight of the tops and length and dry weight of the roots were obtained at the end of the eight weeks' experimental period.

Magnesium and calcium deficiency and toxicity.— The reaction of rice plants to the absence of magnesium and of calcium in nutrient solutions was noted after the second week. Evidence of magnesium and calcium deficiencies consisted of a yellowish chlorosis followed by death and a uniform browning of most of the leaves. A few plants had leaves still living after the eight-week period, although they were greatly stunted. Figures 3 and 4 show the dry weights for these series as well as for the magnesium-free and calcium-free series. The addition of 3 ppm. of magnesium to the solution brought about a sharp increase in growth (fig. 3), but further additions (9, 27, and 81 ppm.) reduced it. The presence of magnesium changed the type of chlorosis from yellowish to whitish. With 3 ppm. of magnesium some of the leaf tips were white with whitish stripes between the larger veins, extending toward the base and closely resembling the early stage of white tip. This chlorosis became less frequent as the concentration of magnesium was increased. Concentrations of 243 ppm. and 486 ppm. of magnesium retarded growth, and all the plants were dead by the second week after being placed in the solution. The only leaf which emerged was so tightly compressed in the leaf sheath that it resembled a spiral of fine wire. This symptom is similar to that described for magnesium toxicity in wheat by Trelease and Trelease (1931).

The addition of calcium to the magnesium-free nutrient solution did not change the yellow chlorosis or appreciably benefit the growth of the rice seedlings. Another type of leaf injury made its appearance in the culture receiving 9 ppm. of calcium, and it became progressively pronounced as this element was increased. During the second week small yellow specks appeared along the margins of the lower leaves and soon involved the entire edge of the leaf, due to enlargement and coalescence of these spots. As the leaf edges died, the spots showed dark brown against a light brown background. In the more severe cases (243 ppm. and 486 ppm. of magnesium) the entire plant became affected. This leaf injury is similar to a type frequently seen in the field during the early part of the growing season, but which is not associated with white tip. In the cultures to which 486 ppm. of calcium were added, 75 per cent of the plants died by the fourth week.

Interaction of magnesium and calcium.—In order to study the effects of calcium on magnesium deficiency and toxicity and the counter-action of magnesium on calcium toxicity, six series of cultures containing varying concentrations of both salts were used. When the cultures contained 3 ppm. of magnesium, the addition of 3, 9, 27, or 81 ppm. of calcium had very little effect on growth or chlorosis. The stunting caused by 9 ppm. of magnesium was overcome by the addition of 3 ppm. of calcium, but the chlorosis occurred occasionally, and 9, 27, or 81 ppm. of calcium produced no further benefits. The addition of 3, 9, 27, and 81 ppm. of calcium to 27 ppm. of magnesium overcame the stunting observed in the calcium-free cultures. The best yields and healthiest plants for the entire experiment were in cultures containing 27 ppm. of each salt. When 243 ppm. of calcium were added to any of the above mentioned magnesium concentrations, a decrease in growth occurred. The stunting produced by calciumfree cultures having 81 ppm. of magnesium was checked by the initial addition of calcium, the greatest improvement occurring with the highest concentration (243 ppm.) of calcium. Cultures containing 243 ppm. of magnesium were toxic to the rice plants, and the additions of 3 ppm. and 9 ppm. of calcium had little effect. Magnesium toxicity was progressively decreased as 27, 81, and 243 ppm. of calcium were added. Magnesium in concentrations of 486 ppm. was toxic in all cultures, and the addition of calcium produced little improvement, although a slight increase in growth occurred in the few plants still living after eight weeks in the cultures to which 81 ppm. and 243 ppm. of calcium had been applied. Since quantities of more than 3 ppm. of magnesium caused progressively greater stunting in calciumfree cultures, it may be assumed that 3 ppm. of magnesium is sufficient to overcome magnesium deficiency in rice seedlings and that larger quantities are toxic in the absence of calcium. The addition of calcium completely antagonized this toxic action, producing growth as great as that in the cultures containing non-toxic amounts of magnesium. No definite magnesium:calcium ratio produced optimum antagonism as evidenced by maximum growth in each series. Magnesium:calcium ratios of 1:1 and 1:3 always produced the best results, but neither was consistently superior throughout the experi-

The most severe calcium injury observed in magnesium-free cultures consisted of stunting and typical brown leaf spots. The stunting was corrected by the smallest addition of magnesium except in the 243 ppm. of calcium series. The characteristic leaf spots, which made their appearance with 9 ppm. of calcium and were even more common with 27 ppm., were absent when 3 ppm. of magnesium were added. The more severe injury caused by 81 ppm. and 243 ppm. of calcium required proportionally high concentrations of magnesium to produce benefits. Injury due to 81 ppm. of calcium was eliminated only in the presence of 243 ppm. of magnesium. The leaf spots produced by 243 ppm. of calcium were never entirely overcome, but the stunting was greatly reduced by the use of larger quantities of magnesium so that the yields with 81 ppm. and 243 ppm. of

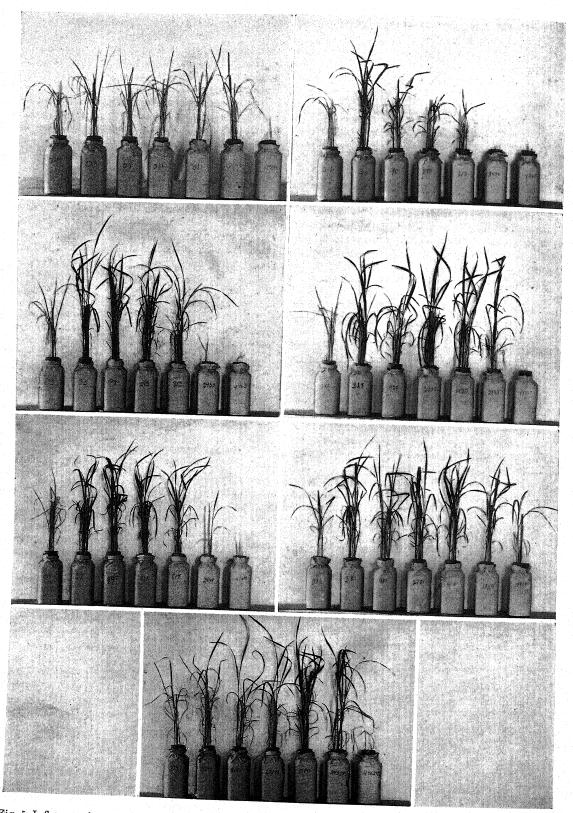

Fig. 5. Influence of magnesium and of calcium on rice plants grown for 8 weeks in the greenhouse. The series at the upper left had no magnesium, and the calcium content varied from 0 ppm. to 486 ppm. The series at the upper right had no calcium, while the magnesium content varied from 0 ppm. to 486 ppm. The rest of the series have 3, 9, 27, 81,

magnesium were next to the best obtained in the experiment. The photographs in figure 5 show the effects of magnesium on calcium toxicity. There was very little change in growth brought about by increases in the calcium concentration in magnesium-free cultures. The best growth occurred when 3 ppm. of calcium were in the solution; higher concentrations reduced growth and caused leaf injury. The corrective value of magnesium for the leaf spots and the tendency to increase yields showed that the highest degree of antagonism takes place when the magnesium:calcium ratio is 1:1 or 1:3.

Dry weights of roots showed that their development under the various concentrations and ratios of magnesium and calcium corresponded to the results obtained from the dry weights of plants. No specific injury was evident on the roots at the time of har-

vesting.

Discussion .- Rice plants were sensitive to changes in concentrations and ratios of magnesium and calcium in culture solution. In the absence of both elements the plants grew very little, the leaves died early and turned a uniform brown color. The response to 3 ppm. of magnesium, without calcium, produced a good yield, although whitish chlorosis was prevalent. Successive increases of magnesium, in calcium-free solutions brought about reductions in growth, and death occurred with 243 ppm. of magnesium. In the absence of magnesium, the addition of calcium in quantities varying from 3 ppm. to 486 ppm. did not increase growth, and the characteristic leaf injury due to excess calcium became more conspicuous as the concentration increased above 9 ppm. of calcium. The benefits derived from calcium in the absence of magnesium were so questionable that it appears that calcium is beneficial only when magnesium is present (Loew, 1903). When both magnesium and calcium were present in the culture solutions, growth increased and leaves were healthier in appearance. The best growth with complete absence of leaf injury occurred in cultures containing 27 ppm. of magnesium and 27 ppm. of calcium. The cultures containing 81 ppm. and 243 ppm. of magnesium plus 243 ppm. of calcium closely approximated these. This indicates that water cultures containing magnesium and calcium in the ratio of 1:1 or 1:3, when both salts are in concentrations of 27 ppm. or more, produce maximum growth during the early growing period of rice plants. The conclusions drawn by Aso (1904) working with rice and Loew (1903) with other cereals correspond closely with the above results. Good growth was obtained when the above ratios were used, and the concentrations of magnesium and calcium were below 27 ppm., but the white chlorosis of magnesium deficiency occurred occasionally on the leaves. In considering the good yields of the cultures containing 3 ppm. of magnesium and no calcium, it must be remembered that these plants did not have conditions of complete calcium deficiency due to the calcium content of the rice seeds themselves. As the magnesium content of the cultures was increased and the calcium content of the seed remained constant, the ratio of magnesium to calcium was increased beyond a point where benefit was possible.

The brown spots which appeared on leaves in the magnesium-free cultures containing 9 ppm. or more of calcium disappeared when magnesium was added

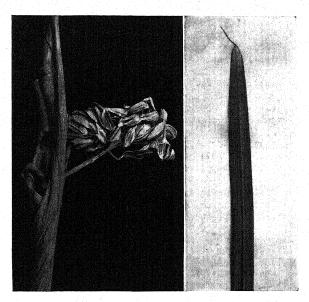

Fig. 6. Typical examples of white-tip injury to rice plants. A (left). Extreme injury showing panicle forcing its way out through tightly whorled boot whose flag leaf was severely damaged by the disease. B (right). Mild white-tip injury observed on lower leaf in culture solution deficient in magnesium.

in sufficient quantity. The reciprocal antagonism between magnesium and calcium in rice plants is shown by the reduction which each of these elements makes in the toxic effects of the other and the stimulus to growth when both are present (Miyake, 1913).

# SUMMARY

Injury observed on leaves of rice plants grown in soil and water cultures, which were low in magnesium content, was similar to a chlorosis observed in the field and known as "white tip." This condition was eliminated in soil cultures when 81 ppm. of magnesium were added and in water cultures with 27 ppm. of magnesium. However, these concentrations of magnesium produced toxic effects, such as stunting and decreased yields, and normal plants were obtained only when calcium as well as magnesium was supplied to the cultures.

Calcium was not toxic in low concentrations in soil cultures. In magnesium-free water cultures 9 ppm.

and 243 ppm. of calcium, respectively, with magnesium varying in each series, reading from left to right, from 3 ppm. to 486 ppm.

or more of calcium produced stunting and brown leaf spots. These injurious effects were not evident when sufficient magnesium had been added.

The greatest benefit from the antagonistic action between magnesium and calcium occurred with the magnesium:calcium ratios of 1:1 or 1:3 when calcium and magnesium were present in concentrations of 27, 81, or 243 ppm. of each element.

# MITOSIS IN LEAVES OF SMILAX 1

# Bernice M. Speese

This is a preliminary report on nuclear divisions in leaves of Smilax L. Two species native at Williamsburg, Virginia, were investigated: S. rotundifolia L. and S. Bona-nox L. The method of preparing the leaves for study was essentially that of Baldwin (1939): fixation for at least twelve hours in Carnoy's fluid, treatment for four minutes with a solution of equal parts 95 per cent alcohol and concentrated hydrochloric acid, and, prior to smearing in iron aceto-carmine, transference again into Carnoy's. The preparations were sealed with a gum mastic-paraffin mixture. Reasons for studying Smilax were several: the leaves are glabrous; they smear well; the chromatic mass is large, and dividing nuclei are, therefore, readily observable. The stage in prophase when the chromosomes are first easily recognizable and the stage in telophase when the chromosomes are still apparent were used as arbitrary limits of mitosis.

The 2n-chromosome numbers of S. rotundifolia (fig. 1) and of S. Bona-nox (fig. 2) were found at leaf metaphase to be 32; the sex of the various plants was not known. (Herbarium specimens of the species will be distributed under the numbers: Baldwin 416 and 417.) The chromosomes in both species vary considerably in size and morphology. Jensen (1937) reported an n-number of 16 for S. rotundifolia from the Blue Ridge Mountains in North Received for publication September 2, 1939.

The writer expresses appreciation to Dr. J. T. Baldwin, Jr., for suggesting and criticizing this work.

Carolina. He interpreted certain of his observations to "suggest a record of previous hybridization for the species." It is of consequent interest to note that counts from leaf mitoses (sometimes considered probably to be chromosomally aberrant) of plants in the Virginia coastal plain corroborate the gametic number determined for supposed hybrid plants in the North Carolina mountains. Other chromosome numbers reported for *Smilax* are:

	2n	$\boldsymbol{n}$	
S. China L		30	Nakajima (1937)
S. glauca L		14	Jensen (1937)
S. hederacea L var. nipponica	30	••	Nakajima (1937)
Maxim.			
S. herbacea L		12-13	Elkins (1914)
		12	Humphrey (1914)
		13	Lindsay (1929; 1930)
S. Oldhami Miq	30		Nakajima (1937)

Of the above workers only Nakajima (1937) got evidence of heteromorphic chromosomes; he reported sex chromosomes of the X-Y type in three species.

Young leaves of S. rotundifolia were used for the determination of the number of nuclear divisions in process for a given area. A leaf of the size shown in figure 3 was fixed at 4:30 p.m. on July 3, 1939; a total of 31,380 mitoses was found in Section A of that leaf; all the tissues included dorsiventrally in the section were examined. There was a general de-

Outlines of two other leaves of S. Bona-nox studied.

crease in mitotic frequency from the proximal to the distal part of that area. Comparable results were obtained from random samples, about one millimeter in diameter, punched from a leaf of the size represented in figure 4; the leaf was fixed at 3:00 p.m. on July 24, 1939; the number of divisions for each of the samples designated in figure 4 was determined: Sample A, 1952; B. 2012; C, 2166; D, 1787; E,

2089; F, 1469; G, 92. It is apparent that the results for Sample E are somewhat "off," but, in general, the basal region appears to be most mitotically active. Leaf shape is dependent upon the frequency patterns of mitosis. Karyokinesis is fundamental to growth and morphogenesis. It would be of some significance to determine for whole leaves the spatial mitotic frequencies and to compare in this regard

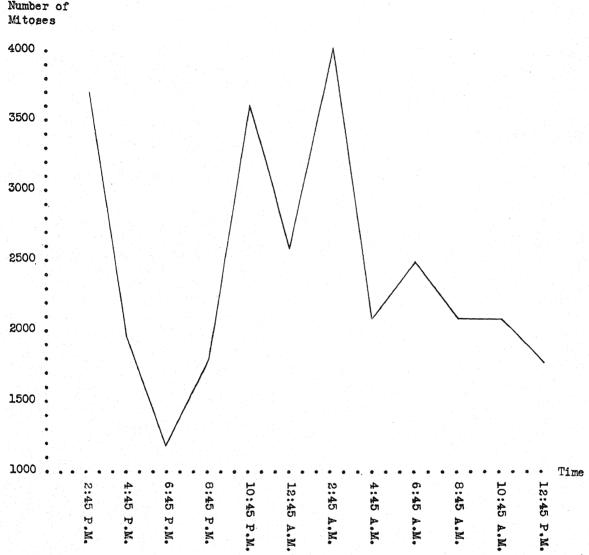

Fig. 8. Curve of division frequency in S. Bona-now leaves fixed one each at 2-hour intervals throughout a 24-hour period.

leaves which differ in shape, as do, for example, the mature leaves of S. rotundifolia and S. Bona-nox (fig. 5).

The literature, reviewed by Friesner (1920), indicates that mitotic divisions occur in waves and are rhythmic. Though, because of the peculiar physiology of leaves, pronounced fluctuations in their division curves might be expected, no analysis seems to have been made of the mitotic rhythms in these plant organs. An approach to this problem was attempted in the present work. Twelve S. Bona-nox leaves of approximately the same size were fixed, one each at 2-hour intervals throughout a 24-hour period on August 2-3, 1939, and smears made of one-millimeter-in-diameter samples, punched from a similar area, located by veins, on each leaf (fig. 6). Since only one young leaf of a given size usually occurred on a single plant of S. Bona-nox, twelve different plants

(growing at the edge of the William and Mary campus) were used. The number of nuclear divisions was counted for each of the samples: Sample A, 2:45 p.m., 3734; B, 4:45 p.m., 2003; C, 6:45 p.m., 1248; D, 8:45 p.m., 1756; E, 10:45 p.m., 3615; F, 12:45 a.m., 2559; G, 2:45 a.m., 3978; H, 4:45 a.m., 2064; I, 6:45 a.m., 2521; J, 8:45 a.m., 2149; K, 10:45 a.m., 2143; L, 12:45 p.m., 1846. These data produce a curve (fig. 8) with two minima-6:45-8:45 p.m. and 12:45 p.m.—and with three maxima—primary maxima, 12 hours apart, at 2:45 p.m. and 2:45 a.m., and a secondary maximum at 10:45 p.m. Since it happened that the leaves fixed at 10:45 p.m. (fig. 6E) and at 10:45 a.m. (fig. 6K) were smaller than the others, two additional leaves of a more comparable size were fixed at these hours on August 17 and August 18, respectively (fig. 7). The number of divisions for the second 10:45 p.m. leaf (fig. 7A)

was considerably lower than for the first (fig. 6E), 3141 as compared with 3615, yet high enough to constitute a marked maximum in the curve. The number of divisions in the second 10:45 a.m. leaf (fig. 7B) did not differ significantly from the number in the first (fig. 6K), 2255 as compared with 2143. These observations on mitotic fluctuations in leaves of Smilax are preliminary, but they support a conclusion reached by Friesner (1920) for roots of several different genera: "the curve of cell division in all plants studied exhibits a number of oscillations in the 24-hour period, in the majority of plants three." Likewise, Ono (1937) found in root tips of Crepis "two marked dividing periods."

#### SUMMARY

Smilax rotundifolia L. and S. Bona-nox L. both have 32 chromosomes at leaf metaphase. Determinations were made from smears.

The number of dividing nuclei was counted for certain selected areas of young leaves of S. rotundifolia. A general reduction in mitotic frequency appears to occur proximo-distally in those leaves.

A temporal frequency established for mitosis in leaves of S. Bona-nox gives a curve with two marked minima and three maxima.

# ROOT ACTIVITY AND THE OXYGEN REQUIREMENT IN RELATION TO SOIL FERTILITY 1

### Kenneth S. Karsten

LIFE MAY be regarded as an unstable equilibrium since energy is involved in the maintenance of this equilibrium. This energy may be furnished directly by the light of the sun or indirectly by the oxidation of carbohydrates or other substances capable of yielding energy upon undergoing oxidation. The importance of the energy relationships of a number of life processes in plants has been realized, and work has been carried out in this field by a number of investigators.

Since the amount of energy released during aerobic respiration of most substances is much greater than that released during anaerobic respiration of the same substances, the factors that influence aerobic respiration are of great importance in any consideration of process-energy relations. Factors that most commonly limit the rate of aerobic respiration are the oxygen supply and the carbon-dioxide content of the medium and the amount and availability of food material.

<sup>1</sup> Received for publication August 8, 1939.

The writer wishes to express his appreciation to Dr. B. M. Duggar for helpful suggestions and criticism offered during the carrying on of this work under his direction in the Botany Department, University of Wisconsin, Madison, Wisconsin. Appreciation is also expressed to Dr. H. G. Petering for acquainting the writer with the use of the dropping mercury kathode and to Mr. D. M. Batson for the gift of a number of soil samples.

Aerobic respiration is necessary for growth in most forms. Allison and Shive (1923) have shown that aeration of sand or nutrient solution cultures of soybeans increased the growth of both roots and tops. Loehwing (1934) showed that the soil atmosphere is normally an important factor in the developmental cycle.

Richards (1938) has given evidence that a given rate of respiration can maintain only a definite amount of protein. Henderson (1934) concluded that the absorption of water by corn roots is accompanied by the expenditure of energy. Mason and Phillis (1936) believe that a part of the energy released during respiration must in some way expedite transport. Many of the workers on the problem of salt absorption and accumulation conclude that respiration determines absorptive activity (see Hoagland, 1937).

The extent and activity of the root systems of plants govern the size and productivity of the aerial parts to a great degree. Root activity is controlled by the character of the soil. The physical, chemical, and biological nature of the soil is being constantly modified because of (1) the presence of living organisms in the soil, (2) the presence of decomposable substances, and (3) the action of external influences. Soil is a dynamic and not a static system,

and changes in the nature of the soil are reflected in the growth of the plants which it supports.

A large number of factors determine soil fertility by their direct or indirect action on the roots of plants. Among these factors are compactness of the soil, pore space, water content, water-holding properties, presence and availability of mineral nutrients, organic content, nature of the organic matter, character and amount of micro-organisms, composition of the soil gases, pH of the soil solution, presence or absence of substances that are toxic to plants, and temperature. A study of soil fertility is difficult, since no single factor can be controlled without changing many or all of the properties of the soil.

The amount and character of the organic matter in the soil are often factors that determine the activity of soil micro-organisms. The oxygen uptake by soil micro-organisms invariably increases with increase in their actiity. As a result, the oxygen content of the soil is lowered and the carbon-dioxide content is raised. Soil temperatures also determine the rate at which micro-organisms lower the oxygencontent and raise the carbon-dioxide content of the soil. If conditions are such that the micro-organisms become so active as to impose anaerobic conditions on the soil, the roots of most plants will be adversely affected by (1) lack of oxygen, (2) high carbondioxide content, and (3) products of incomplete metabolism produced by the micro-organism (see Breazale, 1924; Conrad, 1927).

Poor growth is characteristic of most crops growing under anaerobic soil conditions. The amount of oxygen contained in the soil depends on various soil characteristics. Hutchins (1926) found that the oxygen-supplying power of the soil varies with moisture content and compactness of soil, loosely packed dry soils having the highest oxygen-supplying power.

The amount of literature on the rôle of oxygen in root activity is large. The work accomplished during the period 1668 to 1921 has been reviewed by Clements (1921). The following statement made by Clements in his review is of great interest: "The essential features of the respiration of plants were established in the short period from Ingenhousz (1779) to Saussure (1804). It was shown not only that all organs of the plant possessed this function in common, but also that roots respired in exactly the same manner as stems and leaves, despite the difference in medium. This is supported by practically all the evidence drawn from germination, since the early stages of this have to do with the radicle. In consequence, there is a complete chain of evidence from Mayo (1668) to the present time as to the necessity of oxygen for root activity. The direct proof of this has been obtained by showing the use of oxygen by roots, and this has been confirmed again and again by their behavior in the absence of oxygen."

The work of Boynton, et al. (1938), on the effect of oxygen concentration on apple tree root activities gives us some insight with regard to the importance of oxygen as a factor in soil fertility. They state that when the oxygen in the soil atmosphere is maintained at 3 per cent, the roots are at a subsistence level with regard to oxygen—that is, they continue to live but grow slowly if at all. These workers report that absorption and accumulation were probably inhibited at oxygen pressures below 10 per cent.

Lundegårdh and Burström (1935) studied quantitatively the respiratory activity of the roots of wheat seedlings. From the results of their experiments they concluded that the respiratory activity consists of two parts, the basal respiration, which is necessary for maintaining the roots and for growth, and the anion respiration, which furnishes the energy required for the absorption of anions. They state that the basal respiration is always aerobic and that under no conditions was there any evidence of anaerobic basal respiration. The anion respiration can be anaerobic.

It is readily seen that if the oxygen content of the soil is reduced to such an extent that the rate of basal respiration is radically lowered, the roots of the plants will die, and death of the tops will ensue. If the reduction is not sufficient to cause death but is sufficient to impair the growth of the roots, this condition will be reflected in reduced growth and reduced productivity of the aerial portions of the plant.

Experimental methods and materials.—Since no simple method was available for the quantitative measurement of the oxygen content of soils, the polarographic method of analysis was adapted to this use. The method to be described for the meassurement of the concentration of dissolved oxygen is a modification of the polarographic method, shown by Vitek (1935) to be applicable to the determination of oxygen in solution. The modification used is that of Petering and Daniels (1938). The instrument may be constructed from ordinary laboratory materials and will be referred to as the dropping mercury kathode. See Kolthoff and Lingane (1939) for a review of the theory and applications of the polarographic method of analysis.

Although theoretical interpretations of the polarographic method have been proposed, it may be regarded as an empirical procedure that has been checked against standard methods of chemical analysis. Its use depends on the fact that solutes are reduced or oxidized when a current is passed through a solution at voltages above the decomposition potential. The amount of current flowing depends on the concentration of the reducible material in the solution.

The dropping mercury kathode gives reproducible current-voltage curves because a fresh electrode surface is being exposed continuously. At low voltages, a small residual current flows until the decomposition potential is reached. Then, as the voltage is increased, the current depends directly on the voltage. As the voltage is still further increased, a point is reached after which the current is limited by the rate of diffusion of the reactant to the surface of the mercury drop. The current-voltage curve then be-

comes flat in the ideal case, the current remaining constant until the voltage becomes high enough to produce some other chemical reaction at the kathode. An ideal current-voltage curve is plotted in figure 1.

The portion of the curve OA represents the residual current. At A the decomposition potential is reached. In the region of the curve labeled AB the limiting factor is the rate at which electrons having sufficient energy reach the kathode, the rate of diffusion being much greater than the supply of electrons having the proper energy. At B the current becomes limited by the rate of diffusion of the reducible material to the kathode surface. It may be seen that the portions of the curve, OA and BC, are parallel, and the difference in current B between these two parallel portions of the curve is a function of the concentration of the reducible material in the solution.

Vitek (1935) described the electrode processes for oxygen as occurring in two steps, (1) the reduction of oxygen to oxygen ion, and (2) the reduction of the oxygen ion to hydroxide ion. The first reaction has been found to occur at about 0.1 v and is represented in figure 1 by the portion of the curve that extends from O to C. The second reaction occurs at about 1 v, and the portion of the curve CD represents the beginning of the curve for this reaction.

The apparatus used is represented diagrammatically in figure 2 and is similar to that used by Peter-

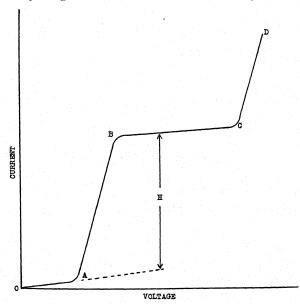

Fig. 1. An ideal current-voltage curve.

ing and Daniels (1938) who showed the application of this method to the measurement of photosynthesis and respiration of algae and to the measurement of respiration of yeast, blood cells, and animal tissue.

WB represents the working battery and is the source of electromotive force for the voltage impressed across the electrodes of the dropping mercury electrolytic cell.

In order to impress a known voltage across the electrodes, a type K potentiometer was used, but a simpler type will serve as well. Large capacity standard cells that deliver the proper voltages may also be used as Petering and Daniels (1938) have suggested.

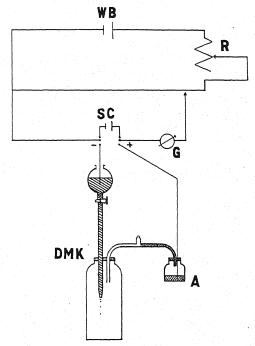

Fig. 2. Diagram of apparatus used in the soil oxygen determinations.

A Weston primary cell marked SC in the diagram is used to keep the potentiometer standardized.

The galvanometer G is of the lamp and scale type and has a sensitivity of  $2.5 \times 10^{-8}$  amps per mm.

The dropping mercury electrolytic cell is represented in the lower part of figure 2. The dropping mercury kathode DMK consists of a reservoir of mercury connected to a section of fine capillary glass tubing. The kathode is connected to the potentiometer by means of a platinum-copper glass sealed lead which is inserted into the mercury of the reservoir. The height of the column of mercury is about 50 cm. and the orifice of the capillary tip is so regulated that from one to two drops of mercury are formed per second. The capillary tip is conveniently made by drawing out thermometer tubing.

The anode A is outside the reaction cell and consists of a pool of mercury in the bottom of a small bottle that contains a solution similar to that being analyzed. The anode vessel solution is connected to the reaction cell solution by means of a KCl-agar bridge. The anode is connected to the galvanometer by means of a platinum-copper glass sealed lead. The anode has an area of about 7 cm.<sup>2</sup> The reaction vessel has a volume of approximately 150 cc.

A 0.1 N KCl solution was used as a medium for the dissolved oxygen. The solution also contained 0.05 per cent gelatin to prevent an absorption maximum and 0.05 per cent thymol to prevent loss of oxygen that might be caused by the activities of micro-organisms.

In these calibrations the oxygen concentration of a solution is determined by sodium thiosulfate titration using the standard Winkler method with man-

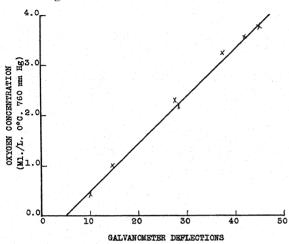

Fig. 3. Oxygen calibration curve for the dropping mercury electrolytic cell used.

ganous sulfate and potassium iodide. Various concentrations of oxygen are obtained by saturating the solution with air and then bubbling nitrogen through this for varying lengths of time.

In using the dropping mercury kathode the solution to be analyzed is placed in the reaction vessel so as to completely fill it. A potential of 0.1 v is then impressed across the electrodes, and the galvanometer reading is noted at this potential. The galvanometer needle moves constantly, since the circuit is disturbed between the falling of one drop and the formation of the next drop. The high reading is taken as the correct reading. For example, if the galvanometer indictor moves from 70 mm. to 78 mm. and then back to 70 mm. continuously, 78 mm. is taken as the proper and correct reading. A potential of 0.9 v is then impressed across the electrodes, and a second reading is taken. The difference between these two readings (at 0.1 v and 0.9 v) is the number that is proportional to the oxygen concentration. When these numbers are plotted against the oxygen concentration as determined by the Winkler method a straight line calibration which is shown in figure 3 is obtained.

A solution of the same composition as that used in the calibration of the dropping mercury kathode is used in the determination of soil oxygen. The solution is boiled under a reflux condenser for 15 minutes to remove dissolved oxygen. The hot solution is then siphoned off into hot 150 cc. bottles provided with glass stoppers, the delivery tube being extended to the bottom of the sample bottle during this operation. The soil sample is taken with a cork borer, and a 3 gm. portion of the core thus obtained is added to

the solution contained in one of each pair of sample bottles. The stopper of the bottle to which the soil sample has been added is replaced immediately, and the bottle is agitated until all the soil gas has been dissolved. The resulting solution is analyzed for oxygen by use of the dropping mercury kathode, the sample bottle being used as a reaction vessel during the analysis. The original boiled solution is likewise analyzed for oxygen. Knowing the volume of the bottle in which the soil sample was placed, the amount of oxygen contained in the sample of soil can be obtained by suitable calculations.

The relation of soil oxygen to soil organic and nitrogen content and to the growth of wheat seedlings was determined as follows. A soil was prepared by mixing two parts of garden loam with one part of sand. To portions of this mixture were added various amounts of starch and of nitrogen as ammonium sulfate. The effects on the growth of wheat seedlings and on the oxygen content of the soil were noted. The soil was not moistened until the seedlings were planted, and all plants were grown in a constant temperature chamber provided with uniform artificial lighting. The temperature of the culture chamber was regulated at 26°C. ± 0.5°C. Intensity of illumination was maintained at approximately 100 foot candles as measured by means of a Weston light meter. Seventy-five watt tungsten filament nitrogenfilled bulbs were used. The wheat grains were germinated at room temperature in pot saucer germinators provided with distilled water. Seedlings were selected for size and planted when the coleoptile had attained a length of 15 cm.

The soil in which the seedlings were grown was contained in specially constructed flower pots which allowed the soil to be watered by a method of autoirrigation. Each pot was provided with a glass tube of 1 cm. diameter which extended upward through the drainage hole of the pot to the extent of 2.5 cm. The tube extended downward from the bottom of the pot for a length of 10 cm. The lower end of the tube was covered with a layer of muslin. The glass tube was held in place in the pot by means of sealing wax. The tube and lower part of the pot were filled with washed dry sand, and the remainder of the pot was filled with the soil under investigation. The soil and sand were wet thoroughly with distilled water, and the pot was lowered over a reservoir of distilled water so that the tube was immersed to the desired depth. With the bottom of the pot 6 cm. from the surface of the water, adequate water content (15 per cent) was maintained in the soil for good growth of the wheat plants. As water is lost from the soil more is taken from the reservoir by capillary action through the sand in the tube. The level of the water in the reservoir was kept as nearly the same as possible throughout the investigations. This type of auto-irrigated flower pot has been operated successfully during three months of continuous use and may be used with either soil or sand.

EXPERIMENTAL RESULTS.—The results of analyses on a variety of soils are given in table 1. The soils were kept in flower pots in the laboratory.

Table 1. Oxygen content of various soils (expressed as milliliters of oxygen at 0°C. and 760 mm. of mercury pressure) per kilogram of soil.

Soil	Water content	$Ml O_2/kilo of soil$
	30%	(3.142
Sandy loam		3.186
	30%	7.500
Superior clay		7.114
Garden loam	(10%	6.667
	20%	3.824
Barnes silt clay loam		4.600
Carrington silt loam		10.622
Miami silt loam		3.200

The results of experiments involving soil mixtures of varying organic and nitrogen content are given in table 2. The oxygen content of the various soil mixtures was determined on the sixth and twelfth days following planting. Growth of the wheat seedlings was measured as fresh weight of the tops per six plants. Five pots of six plants each were used with each soil mixture. Since determinations of the soil in the five pots of each series showed very little variation in oxygen content, analyses were made from one pot in each series so as to disturb plant growth in the other pots as little as possible. The roots of the plants were not sufficient in amount to affect the oxygen content appreciably. The results of this experiment are shown in table 2.

Some idea of the effect of soil oxygen content on the growth of the wheat seedlings can be obtained by plotting the results obtained in this experiment. The curve is plotted in figure 4. The oxygen content of the soil as determined on the twelfth day is plotted on the abscissa, and the growth of the wheat plants as fresh weight of the tops of six seedlings expressed in milligrams is plotted on the ordinate. Naturally some factors other than oxygen content of the soil—e.g., carbon-dioxide content—may have exerted an influence. The pH of the soil was lowered to not lower than pH 5.3 as a consequence of the addition of the starch and ammonium sulfate.

That the lowered oxygen content of the soil mixtures was caused by an increase in the activity of the soil micro-organisms was shown by the fact that such soil mixtures supported a profuse fungus growth. In nearly all cases the soil became compact and hard.

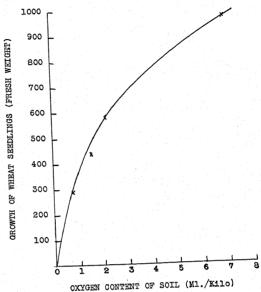

Fig. 4. Graph showing the relationship of soil oxygen content to the growth of wheat seedlings.

Discussion.—The results of these experiments show that the oxygen content of soils varies with the soil type, water content, nitrogen content, and organic content. Soil oxygen content for various soils given in table 1 are less than might be calculated on the basis of pore space and water content. The reason for this is that the composition of the soil atmosphere is modified by the soil micro-organisms with the result that usually the oxygen content of the soil atmosphere is less than that of the external air. Since the soils were kept in pots in the laboratory, the values given may vary somewhat from those that might have been obtained in soils in the field. Soils in the field, however, would be expected to vary to such a large extent that very many samples would

have to be analyzed in order to obtain a representa-

tive average value.

Added organic matter and nitrogen allowed increased growth and activity of micro-organisms which take up oxygen so rapidly under such conditions that the oxygen content of the soil is abnormally reduced. If the oxygen content is diminished sufficiently, root activity is lowered, and the entire plant suffers reduced growth. If the oxygen content of the soil becomes zero, the plants soon die.

#### SUMMARY

The dropping mercury kathode may be conveniently used for the quantitative determination of oxygen in soils. A reduced oxygen content and reduced rate of plant growth resulted from treatments of soil with starch and ammonium sulfate.

### GENERAL SECTION

ABSTRACTS OF THE PAPERS PRESENTED BEFORE THE GENERAL SECTION OF THE BOTANICAL SOCIETY OF AMERICA, COLUMBUS, OHIO,
DECEMBER 28 TO 30, 1939

DECOMPOSITION OF CHITIN BY MARINE BACTERIA. Charles W. Hock, Woods Hole Oceanographic Institution, Woods Hole, Mass.-Chitin-decomposing bacteria have been isolated from sea water, marine sediments, decomposing crabs, and the intestinal contents of marine animals. Although some of the bacteria grow in a medium consisting only of pure chitin in sea water, others require the addition of a readily available source of nitrogen. Acids, reducing sugars, and ammonia have been identified as decomposition products. In an attempt to simulate natural conditions strips of crude Limulus shell were put in jars of littoral sand, bottom mud, and raw sea water. Decomposition of the shell was rapid in the sand, moderate in the mud, and altogether negligible in the water. Carbon and nitrogen analyses of the shell, sand, and mud, were made at frequent intervals, in order to follow changes in the C:N ratio in the system.

OBSERVATIONS ON THE REPRODUCTION OF ULVA LOBATA. Gilbert M. Smith, Stanford University, Calif.—Daily collections were made of plants growing two feet above mean low tide level at Cypress Point near Monterey, Calif. Twice each lunar month there was a conspicuous development of fertile cells at the margins of thalli for three or four days; and then a discharge of all zooids within a day or two. The three- or four-day period of zooid accumulation is the only time in a tidal cycle when there is no tidal exposure of the Ulva during daylight. The period of profuse discharge of zooids occurs on days when exposed plants are reflooded by the tide shortly after daybreak.—In any random collection of individuals about 80% of the fertile plants produce biflagellate gametes and 20% produce quadriflagellate zoospores.-The gametophytes are anisogamous and with female gametes about twice the size of male gametes. Male gametophytes are distinguishable in the field because of their yellowish-green fertile margins. Female gametophytes have grass-green fertile margins but they cannot be distinguished in the field from fertile sporophytes.—The gametophytes are strictly heterothallic. When male and female gametes are mixed in a drop of water there is a clumping of many male gametes about a single female gamete. Both types of gametes are positively phototactic but as soon as a pair begin to fuse the uniting pair becomes negatively phototactic and swims to the less intensely illuminated margin of the drop.—Zygotes and zoospores show the beginnings of germination within two or three days. No partheno-genetic germination was observed of either male or female gametes.

FORMATION OF CELLULOSE PARTICLES IN HALI-CYSTIS SP. Wanda K. Farr, Cellulose Laboratory, Boyce Thompson Institute, Yonkers, N. Y.—The chief visible product of carbohydrate synthesis within the chloroplast is in the form of "paramylum" rings. In the young, disc-shaped plastid there are two small rings, usually arranged so that a line passing through the central axis of each ring lies approximately parallel to the major axis of the plastid disc. As the chloroplast enlarges there is a successive formation of new rings of larger diameter but equal thickness immediately inside the plastid membrane. These larger rings disintegrate within the plastid into uniform-sized particles. After the formation and particulate disintegration of two or more large rings, the chloroplast membrane itself breaks down, releasing into the outer regions of the cytoplasm the entire plastid content. This material of plastid origin goes directly into formation of the lamellae of the cell membrane. The two small rings disintegrate, each into four particles, either before the breakdown of the plastid membrane, after the breakdown of the plastid membrane, or after the deposition of the plastid material in the cell membrane. The uniform-sized particles resulting from the disintegration of the rings formed within the chloroplast are identified as mercerized cellulose by both microscopic and X-ray diffraction analyses.

Ventral specializations of the marchantiales. Marjorie McConaha, University of Iowa, Iowa City, Iowa.—The ventral specializations of six genera were measured and their relations analyzed. The absorptive surface of the thallus may be increased as much as 5480% by its scales and rhizoids. There was a definite segregation of the two types of rhizoids in all thalli examined. Smooth-walled rhizoids emerge from beneath the scales and make contact with the substrate. Regardless of scale arrangement tuberculate rhizoids form a capillary strand beneath each scale and parallel to the thallus. In all these genera the external conduction of water along the thallus is aided by the relations of the ventral organs.

NUTRITION OF THE SPOROPHYTE IN THE MUSCI. Harold C. Bold, Vanderbilt University, Nashville, Tenn., and Barnard College, Columbia University, New York, N. Y.—Until recently the antithetic theory of the nature of alternation of generations has been the dominant one; this has profoundly in-

fluenced morphological studies of the Bryophyte sporophyte. In the light of this view the vegetative activities of this structure are minimized with the implication that such activities are undeveloped or incipient. Studies of the development of the sporophyte in living Musci clearly indicate that photosynthesis begins early in ontogeny and continues nearly to the time of capsule ripening. Although the moss apophysis undoubtedly is actively photosynthetic, photosynthesis occurs in the sporophyte long before it is differentiated as well as in those species where the apophysis is poorly developed. The absence of functional stomata in the capsule of Sphagnum palustris does not prevent photosynthesis in that structure. The sporophyte of Andreaea also is already photosynthetic before it emerges from the venter. The same is true of the sporophytes of Funaria flavicans, Bartramia pomiformis, Dicranum sp. and Pogonatum pennsylvanicum. These studies of the sporophytes of representatives of the three groups of Musci, the Sphagnobrya, Andreaeabrya, and Eubrya, along with the author's earlier published studies of the Hepaticean sporophyte, indicate that the sporophyte of the Bryophyta early in ontogeny initiates photosynthetic activity and is thus largely "independent" of the gametophyte in respect to carbohydrate nutrition. These observations are interpreted as supporting the homologous theory of alternation which emphasizes the fundamental similarity between gametophyte and sporophyte.

PHYSIOLOGICAL STUDIES ON MOSSES. I. THE DE-VELOPMENT OF LEAFY GAMETOPHYTES IN LIQUID MEDIA. Samuel L. Meyer, Miller School of Biology, University of Virginia, Charlottesville, Va.—In the literature on the physiology of the Musci, there appear contrasting and indefinite opinions concerning the development of leafy gametophytes from primary protonemata of normally aerial species in liquid media. Results of investigations with Physcomitrium turbinatum (Michx.) Brid. indicate leafy gametophores develop in liquid nutrient media and that neither direct exposure to air nor attachment to a solid substratum is essential for their development. In the experimental species, both the rate of gametophore development and the number of leafy plants formed are less than on a solid nutrient substrate. Gametophytes grown from primary protonemata submerged in a liquid nutrient medium show pronounced morphological modifications when compared to plants grown normally in

Fertilization in Vallisheria. Robert B. Wylie, University of Iowa, Iowa City, Iowa.—The sperms are formed in the pollen grain and retain their integrity as cells until they emerge from the synergid. One of them soon loses its cytoplasm and is carried as a naked nucleus to the polars. Additional evidence is presented in support of the view that the other sperm retains its organization as a cell until it unites with the egg. Male cells with cytoplasm intact were frequently found in contact with the

egg membrane having been killed during the brief interval between their emergence and fertilization. If a second pollen tube enters the embryo sac, its sperms remain as male cells protruding from the other synergid.

A COMPARISON OF EVOLUTIONARY TENDENCIES IN THE FUNGI, CHLOROPHYTA, AND ANIMALIA. Donald P. Rogers, Oregon State College, Corvallis, Ore.—
The three evolutionary series Fungi, Chlorophyta, and Animalia have separately passed through aquatic, amphibious, and terricolous stages. The similar biological problems of such evolution have been differently met by members of the different series. This difference is most striking in the cytological aspects of the life histories: the Fungi ultimately became dikaryotic, the Chlorophyta retained distinct haploid and diploid generations, and the Animalia early became almost completely diploid. The differences in evolution are evidence of the separateness of the series.

ERIE BLACK AS AN ACETO-CARMINE AUXILLIARY STAIN. B. R. Nebel, N. Y. Agr. Exp. Sta., Geneva. N. Y.—In making chromosome counts on plants and plant parts treated with colchicine it was found that in cases where aceto-carmine alone is not satisfactory—as in axillary buds of apple, pear, plum, peach, apricot, and cherry the following method was successful: Hand section center of bud; kill in 3:1 alcohol acetic acid 10 minutes to 24 hours; alcohol 70 three changes; erie black sat. in 70 alcohol 5 to 25 minutes; alcohol 70 three changes; transfer to slide and dissect meristematic parts in aceto-carmine under binocular; cover, heat, squeeze and seal or add Zirkle fluid for permanent mounting. In sporocyte work erie black may also be employed alone or in combination with aceto-carmine if a dark purple nuclear stain is desired.

A More Graphic comparative life-history chart. Dwight M. Moore, University of Arkansas, Fayetteville, Ark.—Charts showing comparatively the usual outstanding stages in the life histories of the representatives of the various phyla have often been presented on radial lines of comcentric circles. This gives no idea of the relative prominence of the various stages. The present chart shows graphically the decrease in the gametophyte in a heart-shaped area bounded by the lines representing fusion of gametes and meiosis, respectively, and the corresponding increase in prominence of the sporophyte generation. Definite colors are used to indicate various structures, generations or other features.

TEACHING AIDS IN BOTANY. I.—THE PLACEMENT TEST. S. M. Dietz and C. J. Gould, Jr., Iowa State College, Ames, Iowa.—The placement test as used in General Botany at Iowa State College has been developed over a period of twelve years. Prior to 1934 it was used in evaluating student ability but since then it has also been used as a means of sectioning students according to their ability and as a basis for modifying the course for groups and individuals. This placement test, consisting of 10-

16 questions and requiring about an hour for administration, is given at the first class contact. The questions are given in pairs and involve a rating of some of the testable, course objectives which include skills and abilities: in reading, observing, recognizing problems, formulating hypotheses, experimenting, interpreting data and drawing logical conclusions. Each year, 650 students are sectioned into 22 high, medium, or low groups. High sections are given more supplementary materials, more freedom in selection of materials and experiments, a wider range of applied problems and more practice in the use of the scientific method. Acquisition of information plays a more important rôle in the low sections. A comparison of rankings of paired questions of the placement test with their corresponding pairs of questions in the comprehensive final examination affords a valuable teaching aid to the individual instructors by: (1) indicating in which type of section an instructor is most capable; (2) indicating the strong as well as the weak points of individual instructors; and (3) affording a quantitative measure of student progress which is used in teacher-conference groups.

ABNORMAL MICROSPOROGENESIS IN TRADESCANTIA. William L. Brown and Edward C. Berry, Henry Shaw School of Botany, Washington University, St. Louis, Mo.-Abnormal microspores and pollen grains, closely resembling types artificially induced in various Angiosperms, have been found to occur under natural conditions in one individual of Tradescantia subaspera Ker-Gawl. Approximately fifteen percent of the microspores of any given anther are abnormal. This number remains fairly constant throughout the flowering period of the plant. Cell walls frequently fail to form in the diads, resulting in microspores with the unreduced number of chromosomes. In such cases delayed cell wall formation by furrowing is initiated in the microspore or pollen stages. Abnormal microspores possess approximately one-third more refractive granules than do normal ones.

THE NATURE OF THE DIVISION OF THE GENERA-TIVE CELL IN TRADESCANTIA AND POLYGONATUM. O. J. Eigsti, University of Oklahoma, Norman, Okla.—The mitotic features involved in the formation of microgametes were studied for Tradescantia occidentalis (Britton) Smyth. and Polygonatum commutatum (R & S) Dietr. In late prophase, the chromosomes of Tradescantia (n-6) are arranged end to end with the longest dimension of the chromosome parallel to the wall of the tube. The metaphasic stage begins when the chromosomes from each extremity migrate toward a central point. During this process the daughter chromosomes separate and subsequently pass into different nuclei. The chromosomes of Polygonatum (n-20) are arranged upon a definite equatorial plate early in the process, from which the daughter chromosomes separate from each other. The addition of colchicine to the culturing medium prevented the migration of prophasic chromosomes in Tradescantia, and inhibited equatorial plate formation in Polygonatum. The formation of nuclei in the pollen tube continued in the presence of colchicine, resulting in the production of a variable number of nuclei. A cytological analysis revealed that each nucleus contains both daughter chromosomes of the doubled metaphasic chromosome. Upon cursory examination the mitotic processes of the generative cell of these plants seemed different in appearance. however, detailed study disclosed a fundamental similarity between the two. Furthermore, the failure of a complete separation of the daughter chromosomes in the presence of colchicine indicates that the mitotic features of the nuclei of pollen tubes are essentially the same as those of an ordinary mitosis. When treated with colchicine, the formation of nuclei without the separation of daughter chromosomes is an interesting feature of cellular behavior in pollen tubes.

Somatic doubling of chromosomes and nodu-LAR INFECTION IN CERTAIN LEGUMINOSAE. Louise Wipf and D. C. Cooper, University of Wisconsin, Madison, Wis.—Cells having the tetraploid number of chromosomes are occasionally present in the root in the root hair region of the following diploid plants: Pisum sativum L., Lathyrus latifolius L., L. odoratus L., Lespedeza tomentosa Siebold, and Vicia villosa Roth. Such cells are located in the parenchyma of the cortex usually near the endodermis and in the region of young secondary roots. There appears to be a definite relationship between the formation of root nodules in pea and vetch and normally occurring tetraploid cells. Wherever nodular stimulation occurs one or more tetraploid cells are found in the proliferating region of the cortex even though the infection thread has not, as yet, penetrated that area. Later the rhizobia occupy only the cells with the doubled chromosome number. Many infection threads cause no stimulation whatever, even though they pass through several layers of inner cortical cells. In such instances no tetraploid cells were observed in the vicinity of the infection threads. The infection thread has a pathogenic effect on the nuclei of the diploid cells which it penetrates; the chromatin linin net work becomes diffuse, the nuclear membrane assumes irregular shapes, and the nucleus takes a much deeper stain than those of adjacent uninfected cells.

MEIOSIS AND THE CULTIVATION OF EXCISED ANTHERS IN NUTRIENT SOLUTION. Walton C. Gregory, The Blandy Experimental Farm, University of Virginia, Boyce, Va.—The cultivation of excised anthers in nutrient media led to abnormal growth and development in Lilium longiflorum and to cessation of growth in Lycopersicum esculentum, "Bonny Best," and in Datura stramonium. This separation of young anthers from the parent plants led to meiotic failure in all three species. Similar reactions in excised buds and in large cuttings indicate that these effects were not caused by the artificial medium. The normal procedure of meiosis in a grafted cutting of Lycopersicum and its failure

in a similar non-grafted cutting indicates an influence on the part of the stock. It is suggested that the meiotic stimulus is not an inherent property of the sporogenous tissue but is furnished to that tissue by more remote portions of the plant.

THE PHYSIOLOGICAL AND GENETIC EFFECTS OF X-RAYS. Karl Sax, Arnold Arboretum, Harvard University, Cambridge, Mass.—The exposure of cells to X-rays produces two types of response. The first is a physiological effect which results in a partial fusion of metaphase chromosomes and a temporary alteration of nuclear development. Nuclei irradiated at prophase or in the resting stage recover from the physiological effect even though many chromosome aberrations are produced. These permanent aberrations are caused by direct X-ray 'hits" and are lethal in diploid cells only when homozygous deficiencies are produced. chromosome aberrations are referred to as genetic effects since they result in deficiencies or position effects. Either the genetic or physiological effect of X-rays may be cell lethal, and presumably both factors are of importance in radiation therapy.

THE USE OF PERICLINAL CHIMERAS IN TRACING THE GERM-LAYER ORIGIN OF TISSUES IN DATURA. Sophia Satina and A. F. Blakeslee, Carnegie Institution of Washington, Cold Spring Harbor, N. Y. -Seed treatment with colchicine is a new and effective method of inducing periclinal chimeras. In Datura the most frequent chimera type had a 4n or 8n epidermis with 2n internal tissue, but types also were found with 2n epidermis and 4n internal tissue. The cortex may be distinguished from the central cylinder as well as from the epidermis by differences in the chromosome number. Such differences may involve chromosome deficiencies as well as doubled chromosome number. Differences in chromosome number and size of affected cells may be used as labels with which to identify the different germ layers from which they have arisen. The evidence seems to indicate that there are at least 3 definite germ layers in Datura. The dermatogen is found to give rise not only to the epidermis but to contribute to internal tissue.

SEED PATTERNS IN LILIUM AND THEIR SIGNIFI-CANCE. A. B. Stout, New York Botanical Garden, New York, N. Y.—The disposition of seeds in capsules of Lilium allows one to construct charts of the relative positions of various classes of seeds in relation to (1) the abortion of ovules, (2) the pollentube behavior in incompatibilities, and (3) the internal stimulations involved in the development of phenospermic seeds. The seed patterns for the fully self-incompatible triploid Lilium tigrinum clone IN-TERMEDIATE show that at least 50 per cent of the ovules are functional when tested in most successful hybridizations. In various individuals and clones of Lilium candidum there is definite evidence that there are two main types of pollen-tube distribution associated with incompatibility; there is (1) a distal distribution in which the pistil and ovary as a whole limit pollen-tube penetration and (2) there is a scattered distribution in which there appears to be selective relations with individual ovules. The distribution of the different sizes of phenospermic seeds indicate that the size of such seeds depends on the distance from well-developed seeds, and that there is the action of stimulating substances, such as growth hormones, which spread through vascular tissues from fertilized ovules and developing embryos.

INHERITANCE OF SEED-COAT COLOR IN PEANUTS. B. B. Higgins, Georgia Experiment Station, Experiment, Ga.—In the course of an extensive breeding project with peanuts, crosses have been made involving some 16 varieties and strains, including varieties with red, flesh, and white seed-coat colors. Generally the inheritance of seed-coat colors followed very closely the genetical segregations previously reported by other workers. However, one variety, Pearl, with a white seed coat differs from any previously reported in that in every cross made the F<sub>1</sub> seed coats are red. In crosses using Pearl with another white variety, Philippine White, which appears from other crosses to have no factor for color, the F<sub>1</sub> seed coats are red and F<sub>2</sub> red, flesh, and white. The results from all crosses made indicate that the Pearl has factors for both red and flesh colors and also two inhibitors both of which are necessary to prevent development of color.

DEVELOPMENTAL PATTERN OF THE LEAF BLADE IN 2N AND 4N ZEA MAYS AS RELATED TO THE STRUC-TURE OF THE GROWING POINT. E. C. Abbe, University of Minnesota, Minneapolis, Minn., L. F. Randolph, Bureau of Plant Industry, U. S. Department of Agriculture, and Cornell University, and J. Einset, Cornell University, Ithaca, N. Y .-In 2n Zea mays, leaf blades 6 to 12 (counting upwards from the coleoptile) are successively and regularly wider for any given length when compared ontogenetically. Measurements of the growing points at the stages when the primordia of these leaves are being formed indicate that the successive growing points also increase regularly in circumference and volume. Increase in cell number is responsible for this increase in size of the growing points, cell size remaining essentially uniform. The leaf blade initial originates as an equatorial bulge at the base of the growing point in corn. The basal circumference of the growing point is therefore taken as a measure of the initial width of the leaf blade. The successively greater circumferences, due to an increase in the number of cells, are directly reflected in the greater relative widths of the associated leaves. In 2n and 4n corn, an ontogenetic comparison of leaf blades 10 shows an analogous condition, the 4n leaf blade being wider than the 2n for any given length. This greater relative width is correlated with a corresponding difference in growing point volume and circumference. The greater volume of the 4n growing point is, however, due to increase in cell size, cell number remaining the same. There is a corresponding difference in nuclear volumes presumably associated with polyploidy.

STUDIES PERTAINING TO THE LIFE HISTORY OF SPECULARIA PERFOLIATA (L.) A. DC., WITH SPECIAL REFERENCE TO CYTOLOGICAL ASPECTS. J. A. Trent. State Teachers College, Pittsburg, Kan .- A comparative study was made of both open and cleistogamous flowers. Megasporogenesis and microsporogenesis were found to be essentially the same in both kinds of flowers. The archesporial cell in the ovule becomes the megaspore mother cell directly. The usual tetrad of megaspores is produced. The chalazal megaspore becomes the functional one, and through its subsequent divisions, a "normal" embryo sac is produced. The antipodal nuclei undergo rapid divisions giving rise to a multicellular "haustorium." The synergids move into the micropyle and give rise to a micropylar "haustorium." Microsporogenesis follows the usual procedure for most angiosperms. The mature pollen grains are 2-3 nucleate by the time they leave the pollen sac. In the open flowers, the pollen grains germinate on the stigma, and the tubes pass to the ovary through the stylar tissue. In the cleistogamous flowers, the pollen grains germinate within the pollen sac. The tubes penetrate the wall of the pollen sac, reach the stigma, and pass to the ovary in the same manner as in the open flowers. The generative nucleus divides within the pollen grain before germination. Fertilization occurs in the usual manner. Endosperm formation may occur in the absence of triple fusion or even the fusion of polar nuclei. The endosperm becomes fully developed in many instances, in both open and closed flowers, in the absence of an embryo.

POLYPLOIDY AND WINTER HARDINESS RELATION-SHIPS IN THE FLOWERING PLANTS WITH REFERENCE TO KARYOGEOGRAPHICAL PROBLEMS. Wray M. Bowden, The Blandy Experimental Farm, University of Virginia, Boyce, Va.-An investigation of the relationships between chromosome number, degree of winter hardiness, and the geographical distribution of the flowering plants was begun by the author in the spring of 1938. To date some 100 species and varieties pertinent to this problem have been examined cytologically. A brief comparison of certain critically significant species indicates that in most cases the degree of winter hardiness is not correlated with chromosome number differences. Furthermore, the evidence indicates that the degree of hardiness depends upon the genetic constitution of the individual. The whole range of variability in degree of hardiness can be found in either diploid species or in polyploid species. The cases reported in the literature which have correlated higher chromosome number with increased altitude or latitude, apparently illustrate only one of the various types of karyogeographical complexes.

A PRELIMINARY INVESTIGATION OF THE ACENA-PHTHENE RESPONSE SEEN IN CERTAIN SEEDLINGS. A. Orville Dahl, Harvard University, Cambridge, Mass.—Hypocotylous swelling, identical with that seen in colchicine-treated seedlings, was noted in Ipomoea L. exposed to acenaphthene (naphthyleneethylene, C<sub>10</sub>H<sub>6</sub>(CH<sub>2</sub>)<sub>2</sub>) fumes. Certain abnormalities in the curvatures of these seedlings suggest that disturbances of morphological polarity are involved. An experimental series utilizing germinating grains of a pure line of Avena sativa L. which received acenaphthene or colchicine treatment has shown marked swelling of the coleoptilar portion of the embryo as well as a general lack of normally polarized growth. Those seedlings receiving acenaphthene treatment differed from the colchicinetreated series in having greater elongation of the coleoptile as well as a peculiar curvature response which directed the tip of the coleoptile away from the scutellum in the direction of the coleorhiza. Cross-sectional views of the coleoptile indicate that with colchicine treatment the swelling noted is definitely greater than that seen with the use of acenaphthene. Preliminary investigation of the histological aspects of these phenomena indicates that matters of cell size and shape in addition to differential maturation of cells are involved. It seems likely that both acenaphthene and colchicine are capable of causing disturbances which bear no direct relationship to their well-known effect upon the spindle.

THE OXYGEN CONSUMPTION OF ISOLATED WOODY TISSUES. Richard H. Goodwin and David R. Goddard, University of Rochester, Rochester, N. Y.— Thin sections of tissues were cut from the trunks of ash and maple trees with a sliding microtome and their oxygen consumption was measured in Fenn micro-respirometers. In trees collected before bud break oxygen consumption is most rapid in the cambial region. Values for the adjacent secondary phloem and xylem are somewhat lower. In the xylem the rate of oxygen consumption becomes progressively lower as one passes toward the center of the tree, reaching a very low but measureable rate in the heartwood. In trees collected after bud break the rate of oxygen consumption of the cambium, phloem, and heartwood is essentially the same as before bud break. In the newly-formed, differentiating xylem, however, it considerably exceeds the cambial rate. The above relations hold true whether oxygen consumption is expressed per gram of fresh weight or per milligram of nitrogen.

A BOTANICAL SURVEY OF BOIS BLANC ISLAND, MAC-KINAC COUNTY, MICH. Marjorie T. Bingham, Cranbrook Institute of Science, Bloomfield Hills, Mich. -Bois Blanc Island, situated in Lake Huron, between Michigan's upper and lower peninsulas is within the Lake Forest vegetation zone. Within its seventy square miles are widely varied vegetation types, with transition belts so limited or entirely lacking that one passes abruptly from one plant community to another. Spring, summer and fall expeditions have revealed nineteen distinctly different communities composed of approximately six hundred species of plants. On the Lake Huron shores one finds not only the expected differences of high, middle and low beach but within a few hundred feet the character of the shore is totally altered. Shores

of the six inland lakes are unlike the Lake Huron shores. The dominant coniferous forest is entirely replaced in certain sections by pure stands of hardwoods. A few old clearings have assumed the aspect of depauperized meadows, others with more moisture are lush with flowers, many are reverting to forest. Fifty per cent of the island consists of nearly impassable cedar swamp. A small area held in reserve by the United States government has remained primeval forest.

SALT MARSH PLANTS IN RELATION TO TIDE LEVELS ON THE CALIFORNIAN COAST. Ira L. Wiggins, Stanford University, Calif.—An accurate determination of the levels at which Spartina leiantha Benth., Distichlis spicata (L.) Greene, Salicornia pacifica Standley, and Frankenia grandifolia C. & S., grow in eight coastal salt marshes from San Diego to San Francisco Bay shows that these species are confined to definite tidal zones. Spartina grows from about mean sea level to somewhat above mean sea high water. Salicornia grows from a short distance below mean high water upward. Distichlis and Frankenia grow on the higher levels of the salt marshes, never dropping below the plane of mean high water. Where the tidal regime is low these two plants approach closely the level of mean high water, Distichlis growing 0.10 feet and Frankenia 0.28 feet above mean high water at a station where that level is 4.00 feet above mean lower low water. Where the tidal regime is greater both grow at somewhat higher levels. A study of the curves of tidal charts suggests that the lower limit to which salt marsh plants can grow is determined by their response to the average total time of submergence during the twenty-four hours rather than to direct responses to the depth of flooding.

Desert flora of northern peru in an exceptionally rainy year. Harvey E. Stork, Carleton College, Northfield, Minn.—The heaviest rainfall that the desert of the Piura Department of Northern Peru had experienced for many years brought out a dense growth of vegetation in 1939. Most of the growth was produced by five species of grasses and ten species of other annuals, seeds of which can remain viable in the sandy soil during long periods of drought. Several perennials depend upon subterranean storage organs to carry them over the dry years, and two woody species survive by sending tap roots to an eight meter depth.

DISTRIBUTION OF BRIGHT BELT TOBACCO ROOTS IN RELATION TO SOIL PROFILE. L. J. Gier, Campbell College, Buies Creek, N. C.—During 1937 and 1938, the root systems of over 700 tobacco plants, from two soils each of the Norfolk and Ruston series of Harnett County, N. C., were examined. The bulk of the root system for each of these plants was in the plowed A horizon, although many feeding roots extended into the A2. Usually only a single root entered the B horizon. Branching seemed to be determined by the moisture content, soil texture, distance from the stem, and cultivation methods.

There was a definite correlation between the total sands, the total colloids, and the root distribution.

DEVELOPMENT OF THE NUT GRASS PLANT (CY-PERUS ROTUNDUS L.). J. R. Jackson and E. V. Smith, Alabama Agric. Exp. Sta., Auburn, Ala .-The nut grass plant consists of tubers and connecting rhizomes, rosettes of foliage leaves, and umbel-bearing scapes. New plant systems develop from isolated tubers by the growth of apical or lateral buds which produce rhizomes terminated either by rosettes of foliage leaves or by tubers arising by secondary growth of the pericycle of the rhizome. A rhizome which terminates in a rosette of foliage leaves later produces a tuber at the base of the leaves. Any new tuber formed in the system either produces rhizomes from terminal or lateral buds or becomes dormant. A system of more than one hundred tubers may be formed in one season. The plant exhibits both collateral and amphivasal bundles, clearly differentiated cortical and stelar regions, secondary growth by the pericycle, and a cork cambium.

A COMPARATIVE STUDY OF THE SUBTERRANEAN MEMBERS OF SEVERAL CROP PLANTS. Howard J. Dittmer, Chicago Teachers College, Chicago, Ill .-Quantitative data were obtained through counts and measurements of the roots and root hairs of Kentucky bluegrass, winter rye, oats, and soy beans. In soil samples 3 inches in diameter and 6 inches deep, bluegrass had far more numerous subterranean members than any of the other plants, and all grasses greatly exceeded soy beans in number, length and surface area. However, only bluegrass exceeded soy beans in volume. Based on these figures the tap root system of soy beans is very poorly adapted for binding soil. The fibrous root systems of bluegrass, winter rye and oats are far more effective, ranking in efficiency in the order given.

METHODS IN AEROBIOLOGY. O. C. Durham, Abbott Laboratories, North Chicago, Ill.—In studying the aerial incidence and dispersal of pollens, fungus spores and insect particles which are recognized as causes of inhalant allergy, wide use has been made of the gravity method of sampling. Consideration is given to the advantages and disadvantages of various devices for securing rapid deposits of aerial debris and for obtaining volumetric counts. The special problems encountered in taking samples from airplanes over land and water are discussed. Attention is given to a practical technic for preparing and counting atmospheric slides.

CHANGES IN GRASSLAND VEGETATION IN WESTERN NORTH DAKOTA 1932 THROUGH 1939. Warren Whitman, Herbert C. Hanson and Roald Peterson, North Dakota Agricultural Experiment Station, Fargo, N. D.—The period of 1932 through 1939 included two seasons of serious drought in western North Dakota. These occurred in 1934 and 1936. The effects of these drought years on the grassland vegetation were greater than the combined effects of any other factors or groups of factors during this period.

The severe seasonal fluctuations in environmental conditions resulted in wide variations in abundance, density, height growth, seed production, and relative proportions of the constituent species of the grassland communities. These changes, however, were not as extensive nor as striking as those reported from the Central and Southern Great Plains.

The most obvious effect of the two seasons of drought on the grassland vegetation was a reduction in basal area and in abundance of the principal species. The losses incurred as a result of the drought have not yet been fully made up, even after three fairly favorable seasons. Bouteloua gracilis, Agropyron smithii, and Stipa comata were all seriously affected, although the latter species made a remarkable recovery as the result of spread from surviving established clumps and from seedlings. Koeleria cristata was reduced by about 80 per cent, and Andropogon scoparius showed a 50 per cent decrease in abundance. Practically all species have shown appreciable recovery since 1937.

Both annual and perennial forbs were reduced in number during the drought years. In most cases, however, large gains were made in the succeeding years. This was especially true of the annual forbs; the perennials showed less fluctuation. Considered over the whole period of observation both perennials and annuals made a net increase. In only a few cases did they become dominant over any considerable extent of native grassland.

Species senescence. Stanley A. Cain, University of Tennessee, Knoxville, Tenn.—The question of species senescence is considered in connection with the problem of limitation, in the East, of epibiotic species to nunnatak areas. That species senescence is a fact is questioned. It is suggested that the apparent lack of aggressiveness of such disjunct and circumscribed occurrences of a species may have a genetical explanation in the isolation of a relatively homozygous marginal portion of the species population as a whole with a resultant narrower ecological amplitude. This phenomenon, coupled with the limited occurrence of suitable edaphic situations in the region of the epibiotics, is sufficient to explain their local occurrence and lack of competitive ability in most situations. It does not seem necessary to hypothesize species "senescence," and the anthropomorphism may easily obscure true ecological explanations.

PLANT ECOLOGY: THE TWO USES OF THE TERM. Frank E. Egler, Syracuse University, Syracuse, N. Y.—American and European "ecology" have developed under an unintentional isolationist policy, with the result that the term ecology now has a double usage, not adequately recognized, and causing unnecessary confusion and criticism. To exemplify this double usage, seven leading textbooks, covering the same subject matter, are summarized in regard to nomenclature: those of Braun-Blanquet, Pavillard, Reynaud-Beauverie, Coulter Barnes & Cowles, Toumey & Korstian, McDougall, and Weaver & Clements. In Europe, as sciences have

expanded and new sciences emerged, it is accepted that the term ecology is etymologically too restricted to embrace the many fields of knowledge emanating from the original ecology of Haeckel; in America the term, regardless of etymology, embraces all fields of botanical knowledge not orthodox morphology, physiology, taxagents and contributes.

ogy, physiology, taxonomy, and genetics.

VEGETATION OF A HIGH MOUNTAIN VALLEY IN SOUTHERN COLORADO. Francis Ramaley, University of Colorado, Boulder, Colo.—The San Luis Valley is about 100 miles long and 40 miles wide. Annual precipitation is only 8 inches but the water-table of the central part is close to the surface. Ecologically, there are (a) floor, (b) margin, (c) rim. The floor bears a greasewood scrub (Sarcobatus) mixed with rabbit brush (Chrysothamnus). The valley margin supports a growth of undershrubs, low species of rabbit brush, snakeweed (Gutierrezie), and sagebrush (Artemisia), with much grama grass (Bouteloua) and some spring-flowering herbs. The valley rim is foothill country with open pinyon-pine woodland and grama grassland, changing to spruce-pine forest at higher elevations. Plant communities besides those already noted include: river-bottom forest, sedge moor, mixed meadow, sandy-soil grassland, oak chaparral, and aspen groves.

Unrecognized initial stage of plant succession and its prominence in soil erosion control in the south-central united states. W. E. Booth, University of Kansas, Lawrence, Kan.—Five members of the Myxophyceae, usually little thought of as being of great positive economic importance, have been found to be of major importance in the Red Plains Region and oak savannah of Kansas, Oklahoma, and Texas. They form a complete, nonerosive layer over hundreds of acres of badly eroded and abandoned crop land. In addition to erosion control this algal growth is valuable in creating an environment favorable to plant succession.

FURTHER STUDIES ON ZONAL STRUCTURE AND GROWTH IN THE SHOOT APEX OF CYCAS REVOLUTA. Adriance S. Foster, University of California, Berkeley, Calif.-Following the seedling stage, the shoot apex increases notably in size and in plants 40-50 years old may reach a diameter of 2.5-3.5 mm. Associated with this increase in bulk of the terminal meristem, numerous, small spirally-arranged foliar primordia arise from the peripheral zone and develop into the alternating "crowns" of cataphylls and foliage leaves. Although the apices of vegetative and reproductive individuals appear to be fundamentally similar in general zonal structure, the form of the apex varies from a blunt cone to a low truncate mound. Apparently these form differences reflect periodic changes in the relative intensity and distribution of growth in certain zones of the apex. In very broad plateau-shaped apices, the rib meristem zone is reduced in area and activity as compared with the very prominent zone of peripheral tissue in which mitoses are frequent. Conversely, in cone-shaped apices, the zone of rib meristem is well-defined and active. The implication of these facts is briefly discussed with reference (1) to the rhythmical growth of the shoot and (2) to the problem of organization and structural evolution of the shoot apex in gymnosperms.

Embryogeny of torreya nucifera. John T. Buchholz, University of Illinois, Urbana, Ill.—Stages from fertilization onward show nearly all stages in the embryogeny. Cleavage polyembryony is the rule for this and probably other species of Torreya. There are 2-4 archegonia of which usually only one is fertilized, though several cases of two adjacent proembryos in separate archegonia were observed. The proembryo, in which walls form after 4 free nuclei, is confined to the lower one-half or two-thirds of the egg. A dormant winter stage follows the formation of from 12-20 cells, with prosuspensor cells only slightly elongated. Morphological and embryological studies support scheme of phylogeny of Taxaceae suggested by Saxton.

A STATISTICAL STUDY OF TWO VARIABLES IN THE SEQUOIAS—POLLEN GRAIN SIZE AND COTYLEDON NUMBERS. John T. Buchholz and Margaret Kaeiser, University of Illinois, Urbana, Ill.—In Sequoiadendron giganteum the diameters of 500 expanded pollen grains gave a mean of  $22.47 \pm 0.05$  mu ( $\sigma = 1.47$ ). In Sequoia sempervirens an equal number of pollen grains gave a mean diameter of  $32.85 \pm 0.11$  mu ( $\sigma = 2.60$ ). While the extremes overlap slightly, there is no question as to the significance of this difference which is 85.7 times the standard error. The cotyledon numbers were similarly studied in several hundred seeds of these two forms and the results show that the Big Tree has a mean of 3.7 and the Redwood 2.1.

THE EMBRYOGENIES OF BIOTA AND THUJA. Phyllis L. Cook, Ardmore, Pa.—Biota and Thuja repressent two types of embryogeny, the former exhibiting extreme cleavage polyembryony, and the latter, simple polyembryony with only traces of cleavage. The proembryos are similar except for size. Certain of the proembryonic cells assume the rôle of prosuspensors, while the three to five most distal cells contribute the embryos. In Biota each one of these distal cells gives rise to one embryo, while in Thuja, all three to five contribute to one embryonic body. In Biota, each embryonic cell divides, the distal cell remaining embryonic and the proximal becoming the primary suspensor cell. In Thuja, no primary suspensor is formed. Embryonic competition is keen in Biota, entailing great elongation and twisting of suspensors. Several embryos become massive and form secondary suspensors. In Thuja, competition is limited to the number of zygotes, and secondary suspensor formation begins early. After the embryos become massive, tissue development is similar in the two genera, except for the greater size of all structures in Biota.

DEVELOPMENT OF THE FEMALE GAMETOPHYTE AND EMBRYO IN REGNELLIDIUM DIPHYLLUM. Noe L. Higinbotham, Columbia University, New York,

N. Y.—The cell by cell formation of the female gametophyte from the megaspore as well as the development of the fertilized egg into a young plant has been observed in the monotypic genus Regnellidium. As in the related Marsilea and Pilularia, the archegonium is formed at the spore apex, but in Reqnellidium it is enclosed by the folds of the apical papilla. Fertilization is accomplished in about 25 hours. As described for Marsilea and Pilularia, the first division is parallel with the long axis of the archegonium. The following divisions in Regnellidium, however, do not agree with the descriptions given for those other genera. The second division. in the best cases found, is not transverse but is again parallel with the long axis of the archegonium and divides the embryo unequally into four cells. The third division then follows transversely to the archegonial axis. Eventually a cotyledon with a distinct blade is developed and later leaves gradually attain the mature bipinnate form. Regnellidium closely resembles Marsilea and Pilularia, and the bearing of the present data on the relationships within the family is discussed.

THE DEVELOPMENT OF THE EMBRYO OF BARLEY. James Merry, University of Michigan, Ann Arbor, Mich.—The embryonic development of barley was studied in normal embryos and in others excised and grown on nutrient agar. Those excised and cultured showed no further development such as would take place in the ovary, but grew into small plants which fixed the particular stage of the embryo at the time of culturing. A series of such plants from embryos of various ages was studied and the relationships between the parts of the embryo determined. The scutellum and coleoptile are differentiated previous to and separately from the stem axis and are thus considered to be structures peculiar to the embryo and in no way comparable to the lateral organs of the stem.

RELATIVE GROWTH OF DIFFERENT RADII IN CROSS-SECTIONS OF DEVELOPING OVARIES OF IRIS FULVA AND I. HEXAGONA VAR. GIGANTICAERULEA. Herbert P. Riley, University of Washington, Seattle, Wash. In ovaries of giganticaerulea the shortest radius (the septum between carpels) grows faster relative to the radius through the midrib of the carpel than in fulva. The relative growth rates of midrib-radius and longest radius (about 30° from the midribradius) are about the same in both species until the capsule is partially formed at which time in fulva the former grows somewhat faster relative to the latter. The rates of midrib-radius in relation to the radius half-way between the longest and shortest radii (about 45° from the midrib radius) is the same in both species. The 45° radius grows faster relative to the septum in giganticaerulea until about anthesis, when it slows down in that species and accelerates in fulva; these radii are about the same in length in the largest capsules of both species. There is an absolute increase in the size of parenchyma cells of the ovary wall during development.

Final shape depends on the original shape when the ovary is first organized and the relative rates of development of the different radii.

FACTORS RESPONSIBLE FOR THE DEVELOPMENT AND DISTRIBUTION OF THE ENDODERMIS IN MONOCOTYLE-DONOUS PLANTS. D. S. VanFleet, Indiana University, Bloomington, Ind.—Investigations on the formation, distribution and maturation of the endodermis in monocotyledonous plants indicate the presence of an oxidase system associated with endodermal tissue. The extracellular and lamellar location of the oxidases is a factor in the location and ultimate development of the endodermis. All of the characteristic configurations of the endodermal cell. including the Casparian strip and the centripetal thickening associated with many mature cells; is believed to be an expression of a differential in oxidase and antioxidase distribution and activity. The presence of the endodermis in underground stems and its absence in most aerial stems may thus be accounted for. Atmospheric oxygen or organic peroxides in the cortex and enzymatic effusa from the phloem result in an endodermis or mestome sheath whose configuration varies with environmental, cortical and stelar conditions. These conclusions were reached as a result of the microchemical examination or experimental modification of environmental conditions in 86 species distributed through 62 genera and 14 families.

THE OCCURRENCE OF VESSELS IN THE MONOCOT-YLEDONEAE. Vernon I. Cheadle, Rhode Island State College, Kingston, R. I.—All parts of the plants of over 100 species of 75 genera in 18 families were investigated by use of both sections and macerations of the tissues. Vessels were found in the roots of all species investigated. Vessels with only porous perforation plates predominate in only the Agavaceae. Vessels with only scalariform perforation plates predominate in the Amaryllidaceae, Liliaceae, Araceae, Pandanaceae, Bromeliaceae, Strelitziaceae, Trilliaceae, Typhaceae, Zingiberaceae and are found in four species of the Agavaceae. Vessels are found in the stems of a comparatively small number of the species and where found generally have scalariform perforation plates. They are present in the Smilacaceae, Pandanaceae, Palmae, Gramineae and in seven species of the Liliaceae. In Acorus and Monstera there may be a few vessels. Vessels are found in the leaves of even fewer species. They have been noted only in the Gramineae, Palmae, Pandanaceae, Smilacaceae and in Cordyline terminalis and Dracaena fragrans. It is obvious that, aside from the roots, the organs of the plants in the Monocotyledoneae are more often characterized by the absence of vessels rather than by their presence. Futhermore, in the majority of cases, the vessels generally have the more primitive types of perforation plates.

SEPTAL GLANDS IN THE LILIALES. Carrolle E. Anderson, Adelphi College, Garden City, Long Island, N. Y.—The structure of the septal glands was studied in the pistils of two hundred and fifteen

species representing ninety-four genera of the Liliales. These septal glands are intercarpellary spaces lined with a simple or a several-layered glandular epithelium. Glands are not present in all genera and species, but the Juncaceae is the only family studied in which they are completely lacking. The size of the gland varies greatly both as to radial and vertical extent. The position of the glands in respect to the locules varies also, some glands being found only below the locules (basal); some appearing at about the middle of the ovary (median); and some visible only at the top of the ovary (terminal). External secretory pores may be present or absent. Secretions from the glands may be poured out directly through basal pores or grooves; they may flow down from the summit of the ovary through tiny tubes; or they may be secreted through terminal or median pores and then flow down intercarpellary grooves to the base of the floral organs.

THE BORDER-PARENCHYMA AND THE VEIN-RIBS OF CERTAIN DICOTYLEDONOUS LEAVES. Richard R. Armacost, University of Iowa, Iowa City, Iowa.—A survey of seventy species, involving mesophytic leaves from woody and herbaceous plants as well as broad-leaved evergreens, showed that the borderparenchyma invested all minor veins as an unbroken sheath one layer of cells in thickness. Its presence greatly increased the area for mesophyll contacts with the conductive system (from 122 per cent to 238 per cent), while its volume was from 300 per cent to 1100 per cent greater than that of the enclosed vein. Dorsi-ventral extensions (vein-ribs) from the border-parenchyma to the epidermis were present in all these leaves. Experiments showed that these vein-ribs promptly conducted eosin solution to the epidermis from veins of certain categories in every species tested. Evidence indicates that the border-parenchyma and the vein-ribs play an important part in conduction between blade tissues and veins.

THE RELATION BETWEEN PLANE OF CELL DIVISION AND ORGAN FORM IN CUCURBIT FRUITS. Edmund W. Sinnott, Columbia University, New York, N. Y .-Differences in fruit shape in cucurbits are due to differences in growth rate between various dimensions, either during early development or throughout growth. In a number of races differing in dimensional growth rates, the angle between the polar axis of a dividing cell and the longitudinal axis of the ovary was measured for a large number of cells. Frequency of division in a given plane was found to be closely related to growth rate of the ovary in that plane. Whatever determines the plane in which a cell divides is therefore concerned with the control of form differences in the developing organ. Plane of division was found to be most variable in metaphase and least in telophase, indicating that the position of the figure is not established at the beginning of mitosis.

THE PEG OF THE CUCURBITS: A STRUCTURE IN-DUCED BY GROWTH HORMONE? Carl D. LaRue, University of Michigan, Ann Arbor, Mich.—Squash seeds with outer coats removed, germinated horizontally, form pegs on the lower side, but upright, exposed to light from one direction, produce pegs on the shaded side. Upright in darkness they develop pegs entirely around the hypocotyls. If the inner coats are completely removed, pegs are not formed, but if coats are left intact on one side pegs appear on that side. Seeds without inner coats but smeared on one side with 0.1% 3-indole acetic acid in lanolin form pegs on the lanolin side. No transfer of hormone from seed coat to embryo appears after 24 hours germination, but after 48 hours germination such transfer is indicated by tests such as those shown above. Avena tests show a decrease of hormone in inner coats and an increase of hormone in embryos after 48 hours germination. Similar results were obtained with pumpkin and watermelon seeds. It appears that the embryos contain enough hormone for normal growth but require transfer of an additional amount from the inner coat to produce pegs. The peg appears to be the only plant structure known which depends on hormones for its existence.

CELL NUMBER IN THE AVENA COLEOPTILE. G. S. Avery, Jr., H. B. Creighton, Connecticut College, New London, Conn.—In order to better understand the activity of hormones, enzymes, etc. in living tissues, and to evaluate in precise terms any data which may be obtained, the number of cells participating in the reactions must be known. Avena coleoptiles of different lengths (1.5, 4, 10 mm., etc.) were cut into  $100/\mu$  segments. The total number of cells was determined in each successive segment. As the coleoptile grows longer, the total number of cells decreases in each segment, except at the distal end; the longer the coleoptile the fewer the cells in the basal segments. In coleoptiles of all lengths the number of cells in the tip segment is about the same, and the number of cells increases in successive segments from tip to base.

FORM CHANGES IN THE APICAL MERISTEM EURING GROWTH. W. Gordon Whaley, Barnard College, Co-

lumbia University, New York, N. Y.—The shape of the shoot apical meristem of Lycopersicon was studied in three dimensions by the construction of models from serial longitudinal sections. The actual meristematic mass was found to have a roughly spiral shape, the form of the spiral changing as the plant matures. Leaf primordia are formed at the lower, differentiating end of the spiraling meristematic mass.

GROWTH AND DIFFERENTIATION OF CORN PLANTS IN RELATION TO NITROGEN SUPPLY. Ilda McVeigh and Paul R. Burkholder, University of Missouri, Columbia, Mo.—Several inbred lines of corn and their hybrids were grown for 6 weeks in four series of nutrient sand cultures with nitrogen (NH4NO3) varied as follows: 0.2, 0.8, 1.6, 3.2, and 9.6 millimoles per liter of solution. Hybrid vigor, as indicated by fresh and dry weights, varied directly with the nitrogen supply, and to a greater or less degree among the different crosses. Thin sections were prepared for observations on meristems, parenchyma and vascular bundles. In plants grown on limited nitrogen, phloem was poorly differentiated and the pitted xylem elements were small, thin-walled, and filled with protoplasm. In the same lines and crosses, cut at the same age, but grown on high nitrogen, the sieve tubes and companion cells were well differentiated and the pitted xylem vessels were large, thick-walled, and without protoplasm. Diameter of the internodes in all plants varied directly with size of parenchyma cells and amount of supplied nitrogen. Development of terminal meristems was arrested in plants grown on deficient nitrogen. With increased nitrogen, terminal inflorescences developed at different rates in different lines, and more rapidly in heterotic crosses between inbreds than in the inbreds themselves. Heterosis is here related to the ability to use nitrogen. Increase in body size with increasing nitrogen supply is dependent upon the specific growth and differentiation of cells in the different tissues.

### PALEOBOTANICAL SECTION

ABSTRACTS OF THE PAPERS PRESENTED BEFORE THE PALEOBOTANICAL SECTION OF THE BOTANICAL SOCIETY OF AMERICA, COLUMBUS, OHIO, DECEMBER 28 TO 30, 1939

A NEW CUPULE FROM THE LOWER CARBONIFEROUS OF SCOTLAND WITH A NOTE ON THE MORPHOLOGICAL SIGNIFICANCE OF PALAEOZOIC CUPULES. Henry N. Andrews, Jr., Washington University, St. Louis, Mo.—A cupule from the Lower Carboniferous oil shales of Scotland is described as a new genus, the type species of which is Megatheca Thomasi, named in honor of Dr. H. H. Thomas. The cupule is an extraordinarily large (6.2 cm. long) tulip-shaped compression composed of 6 lobes free for twothirds of their length. Prominent surface reticulations are held to represent the original presence of a "Dictyoxylon" cortex. The fossil was found associated with Telangium affine (L. & H.). The hypothesis is put forward that the cupular lobes represent modified (originally sterile) telomes enclosing a group, or groups, of fertile telomes. The latter according to Miss Benson's theory became specialized to form the integument and its enclosed seed.

Additional notes on rotodontiospermum, a medullosan seed. Waldo E. Steidtmann, Bowling Green State University, Bowling Green, Ohio.— Newly discovered material of Rotodontiospermum illinoiense, a medullosan seed from the Pennsylvanian of Illinois, illustrates the presence of a well defined micropyle and slerotestal modifications not observed in the original material.

MALE FRUCTIFICATIONS OF THE MEDULLOSACEAE AS ILLUSTRATED BY TWO NEW SPECIES OF DOLEROTH-ECA. James M. Schopf, Illinois State Geological Survey, Urbana, Ill.-In addition to providing abundant material of Medullosa, aff. M. Noéi, Rotodontiospermum, and Alethopteris, aff. A. serli, coal balls from the Calhoun horizon (upper McLeansboro) have afforded a wealth of material of Dolerotheca. Their morphology and histology is discussed and evidence presented favoring their classification in the Medullosaceae. At the same time the specific uncertainties of their attribution are emphasized which render it unlikely that biological correlation can ever be sufficiently well established to permit taxonomic merging of any of these genera. It is suggested that Heterangium and Heterotheca from the lower Carboniferous are the best examples of pre-medullosan ancestry now known. Male spores of Heterotheca, Telangium and Crossotheca are characterized as "Filicisporic"; those of the medullosan alliance as "Dolerosporic." These spore distinctions may be exceedingly useful in outlining the geologic distribution of two major pteridosperm divisions.

GROSS ANATOMICAL VARIATIONS IN MEDULLOSA, AFF. M. NOÉI. Waldo E. Steidtmann, Bowling Green State University, Bowling Green, Ohio, and James M. Schopf, Illinois State Geological Survey, Ur-

bana, Ill.—The gross anatomy of Medullosa stems, aff. M. Noéi, from the higher McLeansboro Calhoun coal horizon is presented by a series of diagrams. Stelar configurations show considerable variation but most striking of all characters is the distribution of internal periderm. The characteristics of the periderm possibly provide the best available means of judging ontogenetic age of any particular specimen. For taxonomic purposes, the characteristics shown by the primary wood appear to be of considerable significance.

PROGRESS REPORT ON INVESTIGATIONS OF OHIO PSARONII. A. H. Blickle, University of Cincinnati, Cincinnati, Ohio.—Numerous specimens of silicified Psaronius stems have been obtained from beds of Conemaugh and Monongahela ages in Ohio. A number of new species are described and compared with stems previously identified. The status of the present investigation of anatomical and morphological features of the material is reviewed with reference to taxonomic interpretation.

COAL FLORA STUDIES: LEPIDODENDRALES. Fredda D. Reed, Mount Holyoke College, South Hadley, Mass.—Among the many and diverse plant tissues found in coal balls from Harrisburg, Ill., were fragments, both vegetative and reproductive, with ample structural preservation to establish their position in the order Lepidodendrales. Of these fragments there were six species of leaves (Lepidophyllum); rhizome and rootlets of Stigmaria; cone axis, cone scale, microsporangium containing microspores, isolated megaspores of Lepidostrobus; and developmental stages of Lepidocarpon. While it is possible that some of the vegetative and reproductive genera might be related and reduced to the same plant, yet the variation within a genus, as in Lepidophyllum, and the new species reported testify to the variability and complexity of the order.

MAZOCARPON FROM THE HIGHER MC LEANSBORD BEDS OF ILLINOIS. James M. Schopf, Illinois State Geological Survey, Urbana, Ill.—The morphology of well preserved and abundant male and female cones of Mazocarpon is presented. The mega- and micro-spores are characterized and features of the female gametophyte illustrated.

Evidence is presented for favoring a sigillarian alliance for *Mazocarpon* on a somewhat more substantial basis than previously.

With respect to biological considerations it is concluded that *Mazocarpon* has no close affinity with any of the Paleozoic seed-bearing lycopods and retains the essentials of the free-sporing habit. The megasporangium is highly developed to a state incomparable among either the fossil or modern representatives of Lycopsid plants.

A NEW SPECIES OF CORDAITES FROM THE PENNSYL-VANIAN STRATA OF IOWA. L. R. Wilson and A. Johnston, Coe College, Cedar Rapids, Iowa.—Coal ball studies in Iowa have produced many petrifactions, among which are roots, stems, and leaves of Cordaites. An anatomical study of the stems show that they are undoubtedly of a new species and most closely related to Cordaites michiganensis Arnold. The name C. iowensis is proposed for the species.

PROTOLEPIDODENDRON, WITH SPECIAL REFERENCE TO THE UPPER DEVONIAN OCCURRENCE IN SOUTHEASTERN NEW YORK. Harlan P. Banks, Cornell University, Ithaca, New York.—The essential characters of the genus Protolepidodendron are reviewed and its separation from the numerous other early lepidodendrid genera discussed. New species from New York deposits are described and illustrative material exhibited.

SOME RELATIONS BETWEEN PALEOBOTANY AND EVOLUTIONARY THEORY (SUMMARY). Edward C. Jeffrey, Harvard University, Cambridge, Mass .- In recent years the experimental side of the biological sciences has made great progress, a situation which is entirely advantageous. As a consequence the fundamental fact that biology is to a very large degree an historical science is sometimes lost to view. One consequence of this tendency has been the diminished regard for the biogenetic law or the hypothesis of recapitulation. It has been, for instance, objected that the gill arches of the mammalian embryo are not a persistence of structures derived from a fish-like ancestry, but on the contrary represent a physiological adaptation for the respiration of the surrounding amniotic fluid. This criticism loses sight of the unquestionable physiological fact that foetal respiration in the placental mammals is carried on through the blood vessels of the placenta. Further, the young mammal has fish-like segmented musculature. Even the rashest experimentalist could scarcely urge that this corresponds to the necessity for swimming about in the maternal amniotic fluid. Even if the criticisms of the recapitulationary hypothesis outlined above are frivolous and inaccurate, there may well remain a doubt on account of the extreme interval between fishes and mammals.

In the case of the Conifers we have a continuous series from the Paleozoic to the present, which comprises not only external form but important details of internal organization. One relatively ancient group of Conifers is the Araucarians, now confined to the southern hemisphere but once prevalent throughout the world. The Cretaceous Araucarians closely resembled living forms, but presented certain peculiarities, which make impossible the conventional view that they are nearly related to the Paleozoic group, the Cordaitales. It is an interesting fact that the significant characters of later Mesozoic Araucarians are represented in a recapitulationary form in living representatives of the group. As a consequence of this situation, which has many counterparts in the coniferous series, we have to do with the actual persistence of ancestral characters in the young of closely related modern forms. To employ the words of a forceful President of the United States, we have to do with a condition and not a theory, particularly as no flight of physiological imagination can correlate the ancestral structures persisting in modern Araucarians with any physiological utility. The biogenetic law thus received new and very strong support from the side of fossil Conifers.

Another undesirable tendency is to advance theories of relationship or at least of resemblance based on a single character. This situation is well represented by the form genera of Kraus, in which a single characteristic figures as a determinant. Thus we have the terms Araucarioxylon, Cupressinoxylon, Pityoxylon, etc., based on single characters. The absurdity of the classification even from the standpoint of the mere species maker is clear when it is pointed out that all surviving groups of Conifers, except the Abietineae, once had the ligneous characteristics of the Cupressinoxylon type. Further, until recently none of the true Araucarian fossil woods has found a place under the form genus Araucarioxylon. The well known Whitby jet, for example, has been referred to Araucarioxylon under the specific title of A. Lindleyi. Jet as a matter of fact belongs on the basis of recent comparative studies to a group very remotely related to Araucarian conifers. Conversely many woods of true Araucarian affinities beyond question have been referred to Cupressinoxylon. It has been recently proposed to refer all fossil woods to the genera of Kraus. In the words of another forceful President of these United States, this would be going back to the horse and buggy days!

It can not be too strongly emphasized that the identification of fossil remains can only be satisfactorily carried out on the basis of comparative anatomical characters and can not rest on the single features adopted in the system of Kraus or similar classifications based on characters of organization. It may further be added that the evolutionary aspects of wood, than which there is no more continuous or important biological document, can best be studied in the light of the biogenetic law.

The origin of the pteridophytes. Gilbert M. Smith, Stanford University, Calif.—The theory of a direct origin of pteridophytes from algae is discussed. Green algae are shown to be the only potential ancestors and reasons are given for thinking it very improbable that they evolved directly into pteridophytes. Bryophytes and pteridophytes are considered phylogenetically related because of the many common features. The possibility of their derivation from a common ancestor is discussed and then rejected. An origin of pteridophytes from an anthocerotean type of bryophyte is considered the most probable because of the many similarities in sporophytic and gametophytic generations of the two.

LATE TERTIARY FLORAS FROM THE GREAT BASIN AND ADJACENT AREAS: THEIR CLIMATIC, FLORISTIC AND STRATIGRAPHIC SIGNIFICANCE. Daniel I. Axelrod, United States National Museum.—An arid north Mexican flora ranged from southeastern California into northern Mexico during Middle Miocene time, when the redwood forest flora lived in the northern Great Basin and Columbia Plateau. Late Miocene and early Pliocene elevation of the Sierra Nevada-Cascade barrier along the western edge of the province resulted in a lowered rainfall and greater extremes of temperature at the north, allowing the northward migration of many members of the southern element.

Late Tertiary floras distributed from southern Oregon and Idaho southward for 900 miles into the Mojave and Colorado Deserts, show that the members of this group are represented in the three generalized communities which may be distinguished over the area at this time—a montane forest at the north, a central woodland association and a desert-border community at the south.

The nature of the climate over the region is discussed briefly, later Tertiary floristic changes over the region are indicated, and a basis for correlation is presented.

Adolph Carl Noé. Fredda D. Reed, Mount Holyoke College, South Hadley, Mass.

# PHYSIOLOGICAL SECTION

ABSTRACTS OF THE PAPERS PRESENTED BEFORE THE PHYSIOLOGICAL SECTION OF THE BOTANICAL SOCIETY OF AMERICA, COLUMBUS, OHIO, DECEMBER 28 TO 30, 1939

THE TOXICITY OF SULFANILAMIDE IN TOBACCO. Ernest L. Spencer, The Rockefeller Institute for Medical Research, Princeton, N. J.-Sulfanilamide in low concentrations produced marked symptoms of toxicity in Turkish tobacco plants (Nicotiana tabacum L.) grown in sand or water cultures. The first symptom is an interveinal chlorosis near the tips of the youngest leaves. As this becomes more severe, terminal growth is retarded but no necrosis appears. Severe cases are marked by the appearance of many strap-shaped leaves. If the chemical is withheld, plants may outgrow the disease soon after its onset. This type of toxicity is apparently dependent on the structure of the sulfanilamide molecule as a whole, for closely related compounds, such as sulfanilic acid, benzenesulfonamide, p-amino-benzamide, aniline and p-toluene sulfonic acid produced no symptoms resembling those described. Sulfapyridine, which contains the sulfanilamide structure, produced symptoms similar to those described above. A striking similarity was noted between the symptoms of sulfanilamide toxicity and those characteristic of frenching, a physiological disease of tobacco. These observations suggest that frenching of tobacco may possibly be due to the formation, in the plant or in the soil, of an organic toxin similar in structure to sulfanilamide.

THE MINERAL COMPOSITION OF YEAST ASH FROM SPECTROSCOPIC ANALYSIS. Oscar W. Richards and Mary C. Troutman, Research Department, Spencer Lens Co., Buffalo, N. Y .- A pure strain of Saccharomyces cerevisiae was grown in Williams' medium, in Williams' medium enriched, and in malt extract medium. After washing, the yeast was ashed in platinum. Spectroscopic plates were made of ashes of the yeast, of the components of the medium, of autolyzed yeast and yeast extract to determine which elements were present. The following elements were found present in the yeast ash: Ba, Bi, B, Ca, Cr, Cu, Au, Fe, La, Pb, Mg, Mn, P, Pt, K, Ag, Na, Tl, Sn, and Zn. Autolyzed yeast contained Al in addition. Most of the trace elements were present in the asparagine, and the large number of impurities present may be a more important reason for its nutrient value for micro-organisms than its nitrogen content. The importance and origin of the trace elements will be discussed.

GLYCOSIDE FORMATION IN PLANTS FROM ABSORBED ETHYLENE CHLOROHYDRIN, o-chlorophenol and chloral hydrate. Lawrence P. Miller, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y.—In a previous report it was shown that potato tubers and gladiolus corms form  $\beta$ -(2-chloroethyl)-d-glucoside from absorbed ethylene chlorohydrin. Experiments with other plant tissues and with other chemicals have shown that the formation

of glycosides in plants from nonnaturally occurring substances can take place quite generally among the higher plants. A crystalline acetyl derivative of a chlorine-containing glycoside formed in tomato plants grown in sand cultures with chloral hydrate added to the nutrient medium has been prepared and the acetyl derivative of the glycoside formed in gladiolus corms from absorbed o-chlorophenol has also been obtained in crystalline form. Analysis of the latter and comparison with authentic  $\beta$ -o-chlorophenol-d-glucoside tetraacetate showed that, contrary to what might have been expected, the glycoside in question is not  $\beta$ -o-chlorophenol-d-glucoside but a glycoside not yet identified. Similarly, the chlorinecontaining glycoside which has been obtained from tomato plants treated with ethylene chlorohydrin is not identical with that formed by ethylene-chlorohydrin-treated potato tubers or gladiolus corms.

A STUDY OF CELLULAR CHANGES AND DRY MATTER CONTENT IN THE GROWING REGION OF THE PRIMARY ROOT OF COWPEA SEEDLINGS. Mary E. Reid, National Institute of Health, Washington, D. C .- The growing region of the primary roots of young cowpea seedlings was cut into successive segments measuring 1, 2, 2 and 5 millimeters in length, beginning at the tip. Some of this material was used for dry weight determinations of the different regions, and similar material was preserved and sectioned for microscopic study of nuclear and cellular activity, the number and sizes of cells and thickness of walls. The relative sizes of cells in the above segments averaged 1, 3, 14, and 30, and the dry matter 23, 16, 8.4, and 6.2 per cent, respectively. Whereas, a volume increase of 1,300 per cent occurred during the transition of a cell from the condition in the embryonic region to that in the region of elongation (third segment), the dry matter increase was 400 per cent

RELATION OF VITAMIN C TO CELL SIZE IN THE GROWING REGION OF THE PRIMARY ROOT OF COWPEA SEEDLINGS. Mary E. Reid, National Institute of Health, Washington, D. C .- Determinations were made of the indophenol-reducing value (vitamin C) of segments of primary roots of cowpea seedlings similar to those described above. A decreasing gradient extending from the embryonic zone to the region of maturation was characteristic of the vitamin C values obtained per unit of fresh weight, whereas the content of the vitamin per cell formed a gradient in the reverse direction. A gain of over 700 per cent in vitamin C per cell occurred during its transition from the meristematic stage in segment 1 to the phase of elongation found in segment 3. The relative amount of increase in volume of the cell was more than twice that of the vitamin. The increase in dry matter per cell more nearly paralleled that of the vitamin.

ANATOMY OF THE STARCH GRAIN. Sophia H. Eckerson, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y .- The method of study used is that of slow disintegration and watching in the microscope as the structural features are uncovered. A very satisfactory procedure is: treatment of the grains with 7.5 per cent hydrochloric acid for 10 to 30 days (Hanson and Katz) followed by calcium chloride or nitrate on the slide. On the outer part of the grain is a thin membrane-like envelope, elastic and pliable in the young grain from living cells; thicker, hard and brittle on the dry mature grain. Against the inner surface of this envelope is a layer consisting of narrow, concentric bands cemented together by a colloidal substance. In the inner part of the grain is a system of radial strands, spreading from the growth center to the inner surface of the concentric band layer. The concentric bands and the radial strands are made up of microspherites (Wieler)—tiny, globoid, birefringent units, held together in rows by and covered with a viscous, colloidal substance. Photographs have been made of all these structures, both in their natural position in the grain and isolated from the grain.

A DIFFERENTIAL VOLUMETER FOR MICRO-RESPIRA-TION MEASUREMENTS. Kenneth V. Thimann and Barry Commoner, Harvard University, Cambridge, Mass.—A micro-respirometer of differential volumeter type is described. By making the experimental vessel small, the control vessel large, and the capillary very fine, high sensitivity is obtained, while the use of a relatively large surface of KOH allows rapid CO<sub>2</sub> absorption. Solutions can be added quantitatively without disturbing the measurements. A drop movement of 1 mm., which is easily measured, indicates a volume change of about 0.06 mm<sup>3</sup>. A double water-bath and a shaking device with instantaneous release are used. The apparatus enables readings to be made at 1-minute intervals on a single 3 mm. section of Avena coleoptile.

EXPERIMENTS ON THE RELATION BETWEEN RESPIRATION, PROTOPLASM STREAMING AND GROWTH IN THE AVENA COLEOPTILE. Kenneth V. Thimann and Barry Commoner, Harvard University, Cambridge, Mass.—Using the vessel described above, it has been found that auxin, in concentrations which accelerate protoplasmic streaming, produces very little, if any, increase in respiration in coleoptile sections, whether with or without sugar. The specific effects of a number of respiratory inhibitors on growth and on respiration have been studied.

OXYGEN INTAKE AND CARBON DIOXIDE OUTPUT OF DORMANT GLADIOLUS BULBS. Norwood C. Thornton and F. E. Denny, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y.—Gladiolus bulbs, held dormant by storage in moist soil at room temperature, when removed from the soil, show, at first, a very low rate of CO<sub>2</sub> output, which then increases rapidly until a maximum is reached after 24 to 48 hours. Then there is a gradual return to the original low rate. The rapid output of CO<sub>2</sub> in the early stage is not due merely to a release of CO<sub>2</sub>

previously absorbed in the tissue, since  $O_2$  absorption is found to occur concurrently with  $CO_2$  output. Indeed, for the first 10 to 20 hours following the removal of the bulbs from the soil and preceding the rapid increase in the rate of production of  $CO_2$ , the volume of the  $O_2$  absorbed is greater than that of the  $CO_2$  released. Finally, there follows, for as long as 14 days, an equal rate of uptake of  $O_2$  and output of  $CO_2$ . During these tests the bulbs are not exposed to change in temperature, and they remain dormant when planted again in soil.

RESPIRATION AND OXYGEN REQUIREMENTS FOR GROWTH OF NUPHAR ADVENUM AND OTHER WATER PLANTS. Harlow E. Laing, University of Michigan. Ann Arbor, Mich .- Studies of the respiration and oxygen requirements for growth were made with Nuphar advenum, Typha latifolia, Peltandra virginica, Pontederia cordata, Nymphaea tuberosa, Acorus Calamus, Sagittaria latifolia, Sparganium eurycarpum, Asclepias incarnata, and Scirpus validus. A modified Pettenkofer method was used. Moist gaseous mixtures of air, 10, 4.6, 3.0, 1.5, 1.0, 0.4, and 0.1 per cent of oxygen and purified nitrogen were used as media. In some experiments the plant material was immersed in water through which either air or purified nitrogen gas was bubbled. In all species, the rhizomes or corms were able to respire anaerobically for unusually long periods of time without any noticeable injury. The oxygen requirements for growth were found to vary with the species, the optimum being below one per cent of oxygen for Nuphar advenum, 1 to 3 per cent for Peltandra virginica, and approximately 4.6 per cent for Typha latifolia, while Pontederia cordata grew almost equally well in concentrations of oxygen varying from about one per cent to 10 per cent. Maximum root growth occurred in moist air regardless of the species. Observations were made on the effects of different concentrations of oxygen on the leaves of certain species.

HYDROGEN ASSIMILATION IN GREEN PLANTS. H. Gaffron, University of Chicago, Chicago, Ill.— Oxygen and carbon dioxide are the only gases known to participate in large amounts in the metabolism of green plants. Now it has been found that algae of the family Scenedesmus can activate and utilize molecular hydrogen which normally is an inert gas for all plants. When incubated in hydrogen for a few hours in the dark, the algae will begin to absorb hydrogen in connection with several metabolic processes. They reduce metabolites as well as molecular oxygen provided the latter is given in small concentration. Even more important seems the reduction of carbon dioxide in the light with the simultaneous absorption of twice the volume of hydrogen. The oxyhydrogen reaction in the dark and the hydrogen photosynthesis are distinct and separate reactions because the photochemical process is by far the faster one. The rate of carbon dioxide reduction with hydrogen is proportional to the light intensity, but to a certain degree only. If the light intensity becomes too high, the absorption of hydrogen stops and the algae return to normal photosynthesis with the liberation of oxygen.

THE RELATION BETWEEN RESPIRATION AND CATA-LASE BASED ON STUDIES OF INTACT DORMANT SEED AND SEED WITH CERTAIN MEMBRANES REMOVED. Wilmer E. Davis, Kansas State College, Manhattan, Kan. - Seeds were used with dormant embryos that permitted the removal of certain membranes that restrict the gaseous exchange. Seeds of the same lot, both intact and with membranes removed, were placed in an incubator until the respiratory intensity and catalase activity became more or less constant. The respiratory intensity was determined for a number of intact seeds and likewise of seeds with membranes removed. The catalase of each set of seeds was determined when removed from the respirometer. The ratios of the oxygen used by the intact seeds to that of seeds with membranes removed were quite similar to the ratios of catalase of the same in terms of oxygen released.

EFFECT OF THE ROOT ON CHLOROSIS IN THE GRAPE. F. B. Wann, Utah Agricultural Experiment Station, Logan, Utah.

INFLUENCE OF THE VELOCITY OF CRYSTALLIZA-TION ON THE FREEZING POINT OF LIVING TISSUES. B. J. Luyet and Sister Marguerite Sheeley, St. Louis University, St. Louis, Mo.—Determination of the osmotic pressure of living tissues is often accomplished by measuring the freezing point of the extruded sap. Freezing point determinations on the tissues themselves furnish values which are considerably lower than those of the cell sap and which are of doubtful significance. One of the factors responsible for the lowering of the freezing point in tissues is probably the low rate of crystallization. Callow has found that the velocity of crystallization decreases 350 times when one passes from water to a 3 per cent gelatin solution. If a low rate of crystallization lowers the freezing point, then gelatin solutions treated as tissues, should present abnormally low freezing points. In comparable experiments, at a moderate, constant cooling velocity, 2.5, 3.7, and 5 per cent gelatin solutions, sub-cooled to -6°C. and ice-seeded, required about 2, 12 and 45 minutes, respectively, to reach the freezing point (constant temperature level). With 7.5 per cent gelatin no freezing point could be reached and with 10 per cent the temperature did not rise at all.

DIFFERENTIAL INHIBITION OF INITIATION AND DE-VELOPMENT OF ADVENTITIOUS BUDS OF THE HYPO-COTYL OF FLAX. George K. K. Link and Virginia Eggers, University of Chicago, Chicago, Ill.—In the Bison variety of flax, decapitated hypocotyls, completely isolated hypocotyls, and hypocotyledonary segments, produce adventitious buds, some of which develop into flowering axes. Severed and set into sand the axes develop functional roots. Bud primordia of the lower hypocotyl are laid down early but do not develop further in the intact plant; those of the upper third to half, however, are not even initiated until the hypocotyl is decapitated or completely isolated. Each bud primordium, normal or

adventive, of the plant (except in cotyledonary buds) originates in a single, mature, vacuolated enidermal cell, by a transverse division without preliminary increase in cytoplasm. This division is followed by many trans- and longi-divisions. The parent cell does not enlarge until several divisions have occurred within it. It enlarges radially, mostly outwardly. One or more adjoining epidermal cells repeat this performance and become part of the primordium. Cells below the primordium divide and some of their derivatives build the vascular bridge between the vascular systems of the old and new axes. These findings, basic to our studies of the effect of auxins on cellular growth processes in bud initiation and development of flax, incidentally indicate that the adventive bud primordia of flax, derived wholly from mature, but totipotent epidermal cells. offer promising material for tissue culture experiments.

FACTORS INFLUENCING PROTOPLASMIC STREAMING IN THE OAT COLEOPTILE. R. A. Olson, Marine Biological Laboratory, Solomons Island, Md.—The intracellular translocation of substances through living cells is regulated by protoplasmic streaming. An improved method for observation of the streaming in Avena coleoptiles has been made through the use of unilateral darkfield illumination (parallel light beam, lateral light stop in condenser, darkfield stop in 4 mm. objective, water immersion between condenser and constant temperature slide, periplane ocular, coleoptile axis parallel to light beam). Precise determination of velocity of streaming can thus be obtained with ease. This method allowed the use of an objective photographic recording, depending upon the length of the streak on a film made by a moving particle during a given exposure. The effect of various substances on protoplasmic streaming has been determined. No increase in rate was caused by ethylether in concentrations below 10 g./l, by 3-indole acetic acid below 100 mg./l, by methylene blue below 10<sup>-2</sup> molar. At higher concentrations these substances decreased the velocity of streaming. KCN decreased the velocity to about 40 per cent even at concentrations of 0.01 N.

EVIDENCE RELATIVE TO THE SUPPOSED PERMEABIL-ITY OF SIEVE-TUBE PROTOPLASM. Otis F. Curtis and George N. Asai, Cornell University, Ithaca, N. Y .-In a series of articles dealing with translocation, Crafts has repeatedly stated that sieve-tube protoplasm is completely permeable and the cells are incapable of being plasmolyzed. He has proposed that this complete permeability is necessary for and favors the hypothesis that transport is brought about by a pressure flow through passive phloem. It is claimed that the lateral leakage from the permeable sieve-tubes is prevented by the surrounding living parenchyma cells. If the sieve-tubes were permeable to their contents there would probably be leakage along the phloem parenchyma walls, since these lack the casparian strip which is probably effective in preventing leakage from the permeable xylem cells of the root cylinder. Furthermore, if the phloem were

permeable to the contained sap having an osmotic concentration greater than that of the parenchyma cells, the latter would become plasmolyzed and thus open a free path for outward leakage from the phloem. We have found that the phloem exudates from Fraxinus and that from Cucurbita will strongly plasmolyze their respective phloem parenchyma cells. This, therefore, demonstrates that the sievetube membranes cannot be completely permeable to their contents. We have also found it possible to plasmolyze sieve-tubes if precautions are taken to eliminate the disruption resulting from cutting the tissues before making the tests.

INITIAL WATER-SUPPLYING POWER OF DIFFERENT KINDS OF SOIL AT ONSET OF PERMANENT WILTING IN WHEAT AND COLEUS. Burton E. Livingston and Max Wolf, Johns Hopkins University, Baltimore, Md.— At field saturation initial water-supplying power is very great for all kinds of soil, at least as great as one gram per square centimeter for the first hour. At beginning of permanent wilting in ordinary plants, its value-measured by means of porousporcelain soil-point cones with 1-hr. exposure-has been found to vary within the very narrow range between about 2 and about 7 mg./sq. cm./1st hr., being thus practically constant for all soils. This slight variability, which is not clearly related to water-holding capacity or moisture equivalent, has been regarded as probably due to experimental uncertainty of several sorts, but it is now indicated that higher values of this dynamic wilting coefficient are to be expected when the volumetric clay content of the soil is very high. In some recently completed experiments, employing wheat and coleus grown in small cylinders of somewhat loamy clay, muck humus, fine sand, and mixtures of these, the value of the coefficient was shown to be low and about the same (16 mg.-23 mg.) for humus, sand and humussand mixtures, noticeably greater and about alike (25 mg.-35 mg.) for the mixtures in which the loamy clay comprised about one-half of the soil, and much greater (72 mg.) when the loamy clay was used alone. This relation may perhaps have been due to restricted root growth in the most clavey soils.

THE DROUGHT RESISTANCE OF SOME WESTERN GRASSES. Lowell F. Bailey, Grand Rapids Junior College, Grand Rapids, Mich .- The drought resistance of Agropyron Smithii, A. ciliare, and Bromus marginatus is considered from the standpoints of (1) their ability to withstand dehydration without injury, and (2) the ability of their underground parts to remain dormant during periods of drought. Agropyron Smithii loses  $41.6 \pm 1$  per cent of its total water content before permanent wilting ensues. Bromus marginatus and Agropyron ciliare lose  $49.1 \pm 1$  and  $50.3 \pm 1.2$  per cent, respectively, of their total water contents before the onset of permanent wilting. These values indicate only a moderate ability to withstand drought without injury. The subterranean parts of all three species remained dormant during a period of six months of severe drought, and produced new shoots when water was added to the soil. After another drought period of six months' duration, only Agropyron Smithii resumed growth when water was added to the pots.

EFFECT OF RELATIVE HUMIDITY ON GERMINATION of spores of certain parasitic fungi. C. N. Clayton (Introduced by B. M. Duggar), University of Wisconsin, Madison, Wis.—Spores of Venturia inaequalis (Cke.) Wint., Ustilago nuda (Jens.) K. & S., Ustilago hordei (Pers.) K. & S., and Sclerotinia fructicola (Wint.) Rehm were discharged or dusted on clean dry cover glasses which were suspended in sealed containers above sucrose solutions, saturated salt solutions, or water in order to obtain the desired relative humidities, which were computed theoretically. Stratification of atmosphere or solution within containers was minimized and visible condensation upon cover glasses prevented, except at 100 per cent relative humidity, by mechanically rocking the containers in a bath at  $20.0 \pm 0.02$  °C. Ascospores of V. inaequalis after 48 hours in redistilled water and 100, 99.62, 99.43, 99.0, 98.65, and 98.0 per cent relative humidities averaged, respectively, 97.4, 94.4, 50.5, 23.5, 8.2, 0, and 0 per cent germination. Conidia of V. inaequalis after 24 hours in water and 100, 99.6, 99.0, 98.65, and 98.0 per cent relative humidities averaged, respectively, 96.3, 78.5, 52.2, i-14.3, 0, and 0 per cent germination. Some chlamydo-ir spores of U. hordei and U. nuda germinated at 95 per cent relative humidity, none at 93. Conidia of S. fructiola averaged 80 per cent germination in water but failed to germinate at 100 per cent relative humidity and below.

BREAKING THE DORMANCY OF BUDS OF PEAR TREES WITH GLUTATHIONE. John D. Guthrie, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y.—Injection of 50 mg. of glutathione in 10 cc. of water into the cut ends of branches of pear trees induced more buds to grow than on control branches treated with water. This is in agreement with similar results obtained with potato tubers (Amer. Jour. Bot. 24: 734. 1937). The stimulative action of yeast extracts on pear buds observed by Bennett and Skoog (Plant Physiol. 13: 219. 1938) may be due to glutathione.

AN EXPLANATION OF THE ADVANTAGE OF ALTER-NATING TEMPERATURES OVER CONSTANT TEMPERA-TURES IN THE GERMINATION OF CERTAIN SEEDS. Wilmer E. Davis, Kansas State College, Manhattan, Kan.—The employment of alternating temperatures in germination of seeds is especially useful in seeds with membranes that restrict the gaseous exchange. When such seeds are subjected to high constant temperatures in the germinator, both respiratory intensity and catalase activity increase. Duration of this increase depends on the temperature and the extent of the restriction of the oxygen supply; later a decline occurs until both become quite constant however long in the germinator. This condition of the embryo is here designated as fatigue and may pass into a condition of true dormancy. When alternating temperatures are employed there is a rise in both respiratory intensity and catalase activity throughout the period of germination. No perceptible fatigue is apparent. The period of time required at each temperature of the alternation depends upon the extent of the restriction of the membranes and the temperatures employed. The higher the upper temperature of the alternation may be, the shorter is the time required at that temperature, and the longer at the lower temperature in order to prevent fatigue.

A RAPID METHOD FOR DETERMINING THE GERMINA-TIVE POWER OF SOME HARD-COATED, DORMANT SEEDS. Florence Flemion, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y .- It has been previously shown that the viability of various dormant seeds can be determined within a short time by observing the behavior of excised embryos when placed on moist filter paper in Petri dishes at room temperature. Certain seeds, however, may have such extremely tough coats that it is difficult to remove the embryos without injury, and such seeds may also have, in addition, immature embryos. In these cases, certain pre-treatments greatly facilitate excising the embryos. Viability of such seeds, as for example, Symphoricarpos racemosus, can be determined with the following procedure: the coats are treated with concentrated sulphuric acid and the seeds are then xed in moist peat moss and kept at 5°C. for sevsal weeks until the embryos have imbibed water and developed sufficiently so that they can be excised and the viability determined within 10 days thereafter. A period of one week in moist peat moss before excision also facilitates carrying out the test for other dormant seeds such as Japanese quince, fringe-tree, etc., as well as the hard-coated chokecherry and wild plum, because not only is the excising easier but the subsequent development on moist filter paper takes place more rapidly.

The development of excised maize embryos in an atmosphere of nitrogen. Carl D. La Rue and James Merry, University of Michigan, Ann Arbor, Mich.—Observations were made on the growth of immature excised embryos of Zea mays in artificial culture on plain nutrient agar with sugar, in air and in nitrogen. The excised embryos in air showed little embryonic development but germinated and grew as small seedlings. In an atmosphere of nitrogen, the growth of the root and shoot was inhibited; the embryos did not germinate as did those in air, but showed a development more closely approximating that of the normal embryo in the ovary.

Cause of decreased Germination of bean seeds soaked in water. H. Clyde Eyster, University of South Dakota, Vermillion, S. D.—There are several experiments which prove that bacteria are not the only cause for the decrease in the germination of bean seeds which have been previously soaked in water. (1) The deleterious influence of the soaking process is much less severe at room temperature than at 10°C., at which temperature the bacteria are less active. (2) The proportion of bean seeds which germinate after having been soaked in running tap water at 13°C. for 3 days is the same as that of bean seeds which germinate after having

been soaked at 13°C. for 3 days in stagnant tap water, in which bacteria accumulate. (3) Sterilized bean seeds soaked in sterilized water germinate more poorly than control seeds. The decrease in germination of bean seeds which are previously soaked in water is due primarily to an alteration in the differential permeability of the cytoplasmic membranes. Chemical analyses of the water in which the seeds have been soaked show that there is a loss of proteins and protein constituents from the soaking seeds, and that the remaining germinative capacity of the seeds is inversely proportional to this loss.

GERMINATION OF SEED OF POA COMPRESSA L. AND POA PRATENSIS L. AT DIFFERENT ALTERNATING TEM-PERATURES. Alice M. Andersen, U. S. Department of Agriculture, Washington, D. C.—Seeds of Poa compressa and P. pratensis were sown on soil moistened with water, and on filter paper moistened with water or with N/50 potassium nitrate solution. Germination was studied at 16 different alternating temperatures for a period of 28 days. The plants were placed at low temperature for 18 hours and high temperature for 6 hours daily, except when 4 hours is stated for the high temperature. All temperature chambers were dark, except when light is stated. With seeds of P. compressa, the highest percentages of germination were obtained under the following alternating treatments: room and 30°; 15° daylight with fan and 30°; 15° daylight with fan and 30° for 4 hours; 20° and 30° daylight. In this series, about 80 per cent germination was obtained on soil, 50 per cent on filter paper moistened with water, and 90 per cent on filter paper moistened with nitrate solution. A slightly lower percentage of germination was obtained with the alternations as follows: 12° and 30° daylight; 15° daylight with fan and 35°; 20° and 30° daylight for 4 hours; 12° and 30°; 15° with fan and 30°; 10° and 30°. In these, 60 per cent germination was obtained on soil, 35 per cent on filter paper moistened with water, and 85 per cent on filter paper moistened with nitrate solution. Less favorable alternating temperatures were: 15° with fan and 30° for 4 hours; 12° and 30° daylight for 4 hours; 10° and 30° for 4 hours; 12° and 30° for 4 hours; 20° and 30°; 20° and 30° for 4 hours; 10° and 35°. In this group, about 55 per cent germination was obtained on soil, 25 per cent on filter paper moistened with water, and 80 per cent on filter paper moistened with nitrate solution. Seeds of P. pratensis gave practically the same percentage of germination with all 3 substrata. The highest percentage of germination (about 90) was obtained with the following conditions: room and 30°; 12° and 30° daylight for 4 hours; 12° and 30° dark for 4 hours; 20° and 30° daylight. A slightly lower percentage of germination (about 85 to 88) was obtained with all the other alternating temperatures, except 10° and 35°, and 15° daylight with fan and 35° which gave about 80 per cent germination.

GROWTH OF CEREAL PLANTS FROM DRY AND SOAKED IRRADIATED GRAINS. Edna L. Johnson, University of Colorado, Boulder, Colo.—Dry and soaked wheat

seeds were exposed to X-ray doses ranging from 1,000 to 60,000 r-units; barley and sorghum, to doses not exceeding 10,000 r-units. Doses up to and including 10,000 r-units did not affect survival of seedlings from dry wheat and barley seeds; 5,000 r-units given soaked grains greatly reduced survival while heavier doses were lethal; but 10,000 r-units and under, given sorghum seeds did not affect seedling survival. Noticeable height increases were apparent in all three species on exposure to 1,000 and 5,000 r-units. Three groups of dry wheat seeds, one each of soaked wheat, dry and soaked barley, and soaked glume-free sorghum seeds exceeded controls both in height to tip of highest leaf and to tip of head. Plants from dry, glume-free sorghum seeds given 1,000 r-units were taller than the controls. Tillering was considerably increased in practically every group of wheat plants which survived the given dose. Barley from soaked seeds tillered slightly more than the controls. Sorghum plants from glumefree irradiated seeds had a high percentage of plants with more than one main shoot.

FLOWER PRODUCTION IN DIGITALIS AND CRASSULA RUBICUNDA BY LOW TEMPERATURE AND LIGHT. John M. Arthur, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y .- Both Digitalis and Crassula rubicunda were grown in the greenhouse with night temperatures as low as 55°F. for several years without flowering. At this temperature, flowers were not produced under either long days or short days. Digitalis plants set out-of-doors in September came into flower the following June. Plants transferred to an unheated greenhouse on January 11 flowered in June. When the plants were held in a cold room at 50°F. each night and kept in the greenhouse each day from May 14 until September 30, and then given a long day and a night temperature of 55° to 60°F., flowering occurred in November. Flowers were produced on Crassula rubicunda by similar cold-night treatments except that the low temperature was given from November 14 until April 26. One plant removed from the cold treatments in February produced vegetative branches but no flower buds.

THE ABSORPTION SPECTRA OF WATER EXTRACTS OF SEVERAL SPECIES OF PHOTOSYNTHETIC PURPLE BAC-TERIA. C. S. French, University of Chicago, Chicago, Ill. (Introduced by J. T. Buchholz, University of Illinois, Urbana, Ill.).—In purple bacteria the pigments which absorb the light used for photosynthesis exist in solution combined with a protein. Treating a suspension of these bacteria with supersonic vibration breaks the cell wall to liberate the juice containing two pigments, bacteriochlorophyll and a carotinoid. Both are attached to a protein which makes these substances soluble in water when they are otherwise soluble only in organic solvents. This complex, called photosynthin, can be precipitated and redissolved by changing the salt concentration or the pH of the solution. Such solutions will act as photocatalysts for oxidation of ascorbic acid. Extracts have been prepared from four species, Spirillum rubrum, Rhodovibrio sp., Phaeomonas sp., and Streptococcus varians, and their absorption spectra measured in the visible and near infra-red. The main band of the bacteriochlorophyll occurs at 875, 855, or 840 m $\mu$  depending on the species, while its secondary bands are at 790 and 590 m $\mu$  in all the bacteria examined. The position and height of the bands are the same in the live cells and in the extract. The ability of the organisms to carry on photosynthesis is believed to depend on the properties of this chromoprotein.

Use of the dropping mercury electrode in PHOTOSYNTHESIS STUDIES WITH CHLORELLA PYRE-NOIDOSA. W. E. Moore and B. M. Duggar, University of Wisconsin, Madison, Wis.—The following are among the many advantages of the method discussed: no pre-treatment, smaller amount, and less concentration of algae required; accurate measurement of transmitted light; very rapid; apparatus simple in manipulation, flexible, and portable; small changes measured; special nutrients may be used; duplicate set-ups for simultaneous runs; and at any point the oxygen level is instantly known. Suggestions to aid in the successful application of the method are included in this report. With a number of culture solutions and under different acceptable physical conditions for growth there is little variation in the values for the quantum efficiency. The efficiency as measured is lower than the value reported by Warburg. Data for the quantum efficiency under the following conditions are presented: rate of growth; various inorganic media (Warburg, modified Warburg, Emerson, sea-water, A-Z in water, soil extract, city water, tin distilled water, Pyrex distilled water, and lake water); organic additions to the culture; different light intensities for growth and for the efficiency measurement; effect of the transfer from high light to low light intensity; efficiency from two light intensities alone with no dark period; algae from different sources; attempts to kill the cells and continue the run.

THE CONTRIBUTION TO PHOTOSYNTHESIS OF LIGHT ENERGY ABSORBED BY CAROTENOIDS IN THE DIATOM NITZSCHIA CLOSTERIUM. Herbert J. Dutton and Winston M. Manning (Introduced by B. M. Duggar), University of Wisconsin, Madison, Wis.—A study has been made of the quantum efficiency of photosynthesis in the marine diatom Nitzschia closterium, using low intensity light of wave lengths 660, 546. 436 and 405 m $\mu$ . In conjunction with these experiments, a quantitative study was made of the light absorption by the different pigments in this diatom. In contrast to green algae, N. closterium was found to contain a large amount of fucoxanthin but little or no chlorophyll b. The quantum efficiencies were found to be of the same order of magnitude as those found in this laboratory for the green alga Chlorella. A greater quantum efficiency for photosynthesis in N. closterium was found at wave lengths where a large fraction (30 to 70 per cent) of the absorption was due to fucoxanthin and other carotenoid pigments than at wave lengths where nearly all of the

light was absorbed by chlorophyll. These results strongly indicate that light absorbed by pigments other than chlorophyll can be utilized by this diatom

in photosynthesis. EFFECTS OF MONOCHROMATIC ULTRAVIOLET RADIA-TION ON THE GROWTH OF FUNGOUS SPORES SURVIVING IRRADIATION. Albert E. Dimond and B. M. Duggar, University of Wisconsin, Madison, Wis.—Spores of Rhizopus suinus Niels, were exposed to varying dosages of radiation of wave length 2,650 Å., and measurements of the growth of survivors were made under three sets of conditions. First, photomicrographs were made of hyphae in hanging drops at frequent time intervals, and, after enlargement, the areas were determined with a planimeter. Growth curves of individuals over 4-10 hours were established in this manner. The growth response of irradiation survivors was much more variable than was that of unirradiated individuals; also a number of hyphae from irradiated spores grew at a significantly more rapid rate. Second, the growth on Petri dishes of colonies from irradiated spores was compared with that of unirradiated spores. During the time period of 1.5 to 30 hours after the beginning of incubation, the growth rate of the two types of mycelium was identical. Third, comparatively dry weights of mycelial mats produced in liquid culture were followed. From 36 hours onward, growth of the two types of culture proceeded at the same rate. However, growth continued for a longer period in cultures produced

PHOTOCHEMISTRY AND ABSORPTION SPECTROSCOPY OF THE PYRIMIDINE COMPONENT OF VITAMIN B<sub>1</sub>. Fred M. Uber and Louis A. Fourt, University of Missouri, Columbia, Mo.—Ultra-violet absorption curves for 2-methyl-5-ethoxymethyl-6-amino-pyrimidine show a marked dependence on pH, exhibiting two distinct maxima for a pH of 7.0 or more but only one maximum for a pH of 6.4 or less. The positions of the maxima shift with pH. Molecular extinction coefficients vary greatly with molar concentration, particularly for solutions less than 0.000,1 molar. Beer's law is not obeyed at a pH of either 4.8 or 7.8, and presumably not at others. Irradiation of phosphate buffered solutions, pH 4.8 and absorption maximum of 2,480 Å, resulted in a rapid decrease of the selective absorption. This photochemical decomposition of the pyrimidine has been found to yield ammonia nitrogen.

by irradiated spores. This resulted in the production

of fungous mats which were 20 per cent heavier than

mats from untreated spores.

ULTRA-VIOLET INACTIVATION OF THE PYRIMIDINE COMPONENT OF VITAMIN B<sub>1</sub>. Frank Verbrugge and Fred M. Uber, University of Missouri, Columbia, Mo.—Inactivation of 2-methyl-5-ethoxymethyl-6-amino-pyrimidine has been brought about by irradiation at a wave length of 2,537 Å. The irradiated solution had a concentration of 0.000,125 molar and was maintained at pH 4.8 in a phosphate buffer. Tests for inactivation were made with cultures of Phycomyces Blakesleeanus, 0.05 cc. of the above solution being added to 250 cc. of nutrient medium

and then aliquotted to 10 flasks, which were inoculated with sterile spores of the organism. Thiazole was present in all flasks at a constant concentration, which was twice the molar concentration of the non-irradiated pyrimidine used as a control. Growth curves of dry weight of cultures as a function of pyrimidine concentration gave a basis for the estimation of the inactivation. These curves were linear in the range  $0.0125-0.15 \times 10^{-7}$  molar for cultures grown for 10 days at  $24^{\circ}\mathrm{C}$ .

EFFECT OF LIGHT OF DIFFERENT WAVE LENGTHS ON PLANT GROWTH. F. W. Went, California Institute of Technology, Pasadena, Calif.—Leaf growth, growth in length, phototropism and chlorophyll formation in etiolated pea seedlings is greatly affected by small amounts of light. The spectral sensitivity of each of these processes is very different, indicating that different pigments and different lightsensitive reactions are involved in each process. Thus leaf growth is most pronounced in red, less in yellow and blue, and still less in green, so that its absorption spectrum resembles that of chlorophyll. Growth in length is most decreased by yellow, and least by blue light. Phototropism only occurs in blue and green, confirming older work, and indicating light absorption by carotenoids. Chlorophyll formation is equal in red, vellow and green, but distinctly less in blue.

EFFECTS OF LIGHT QUALITY ON SERRATIA MARCES-CENS. K. W. Kreitlow (Introduced by Lewis H. Flint), Louisiana State University, University, La. -Radiation studies on Serratia marcescens were carried out by growing tube cultures of the organism on Difco nutrient agar and exposing the cultures to General Electric red, blue, and daylight fluorescent lamps. Controls were kept in darkness by wrapping the culture tubes in black photographic paper. Seven isolates of Serratia marcescens were used in these studies and all were found to respond similarly under any particular light quality. The most intense pigmentation was found in cultures grown in the dark and under red light. Less pigmentation occurred in tubes grown under daylight or white light. Cultures grown under blue light gave very slight to no pigmentation whatsoever. Best results were obtained after three or four serial transfers of the organism under light of a particular quality. Maximum gain or loss of pigment resulted after 72 hours of exposure to light of any quality with the cultures being incubated at 20°C. Decrease in pigmentation was also observed when cultures were grown in plain glass tubes exposed to ultra-violet radiation; this loss of pigment was probably due to short blue rays since exposure under filters transmitting only ultraviolet radiation gave almost normal pigmentation.

AUXIN CONTENT IN OVARIES AND YOUNG FRUITS AT DIFFERENT STAGES OF DEVELOPMENT. F. G. Gustafson, University of Michigan, Ann Arbor, Mich.—Various stages of young ovaries and fruits have been used for this study. It may be said that in general the ovaries in the flower bud stage contain more auxin per unit weight of material than do the ovaries

of the flower, and as the ovary develops into a fruit there is usually a further decrease.

AUXIN CONTENT IN CUSCUTA AND ITS HOST. F. G. Gustafson, University of Michigan, Ann Arbor, Mich.—Extraction of the growth hormone with ether showed that the part of the host actually attacked by the Cuscuta had a much higher growth hormone content than that part not attacked by the parasite. That part of the Cuscuta actually in contact with the host had also a higher auxin content than the young free part of the parasite.

Some chemical agents in the production of OVERGROWTHS ON PLANTS. Michael Levine, Montefiore Hospital, New York, N. Y .- The effects of indole butyric acid and a-naphthalene acetic acid were studied on a large series of plants such as Ricinus, Cosmos, Helianthus, Lycopersicon, Datura, Brassica oleracea botrytis, Nicotiana glauca, Rosa, Tagetes erecta, and Kalanchoe Daigremontiana. Tryptophane, indole, and a mixture of tryptophane and Phytomonas tumefaciens were also tested on a similar group of plants. Indole butyric acid and a-naphthalene acetic acid produce massive reactions without roots on decapitated sunflower and Jimson weed. On Kalanchoe, broccoli, and Cosmos, these chemicals induce intumescences with roots. Scalelike organoids appear on the Kalanchoe and broccoli. Tryptophane and indole produce small globular masses on the broccoli and N. glauca, while a mixture of tryptophane and P. tumefaciens produce discrete crown galls. Suspensions of Sudan III, Sudan IV, p-aminoazo-benzene, 2-amino-5-azotoluene, and Grubler's scharlach red were also tested on similar plants. These dyes induce only swellings; yet some of these chemicals are known to be carcinogenic for animals. Heteroauxin-induced overgrowths, under microscopical examination, show close resemblance to crown gall tissue. These "chemical tumors" represent a protective mechanism against an irritating agent.

THE RELATION BETWEEN RESPIRATION, PROTO-PLASMIC STREAMING, AND AUXIN TRANSPORT IN THE AVENA COLEOPTILE. H. G. du Buy and R. A. Olson, University of Maryland, College Park, Md.—The hormone phenomena of vernalization are dependent upon translocation of certain substances through living cells. Protoplasmic streaming regulates the intra-cellular part of translocation; respiration regulates the streaming velocity, and thus the translocation. The Heyrovsky polarographic method has been adapted to a dual microrespirometric method for oat coleoptiles. A marked change in respiration rate below a certain O2-tension has been observed, the critical oxygen tension varying with age. Similar age-effects have been found by others for protoplasmic streaming. Since the reduced rate of respiration after KCN inhibition parallels that of the reduced respiration rate below the critical tension, it is suggested that the respiration system operating at low O2-tension and that not inhibited by KCN are the same. 2-4-dinitrophenol inhibits both the rate of respiration and streaming to the same degree. 3-indole acetic acid alone or in the presence of fructose has no effect on respiration except above 100 mg./l. where it decreases respiration and streaming. Since the protoplasmic streaming persists at the lower respiration rate below the critical oxygen tension, the streaming does not depend upon one specific respiratory system. Direct transport measurements in oat coleoptile cylinders treated with KCN show that the transport of growth regulators is decreased to the same extent as the respiration and the streaming. The concept concerning translocation put forward in Biodynamica 36 (1938) obtains herewith further support.

EFFECT OF VARIOUS GROWTH REGULATING SUB-STANCES ON THE GROWTH OF LETTUCE SEEDLINGS (VARIETY GRAND RAPIDS). R. B. Stephenson (Introduced by H. G. du Buy), University of Maryland, College Park, Md.—Lettuce seedlings are cultured (1) as whole plants, (2) roots and shoots separately, (3) roots and shoots in the same flasks, in sterile media to which special substances have been added in concentrations of 0.1 and 1 mg./l. Thiamin and nicotinic acid-treated roots have nearly the same total growth, but branching in nicotinic acid (and naphthylacetamid) is profuse, and minimal in thiamin. Thiourea on roots alone has little effect, but on entire seedlings it produces the largest root system of all series. Naphthylacetamid has the same effect, but less pronounced. Thiourea definitely retards the growth of a pathogenic Fusarium sp. added to the cultures. Roots treated with naphthyl and indole acetic acids are markedly inhibited in their elongation but produce the greatest number of lateral root primordia. Treated shoots produce from two to three times the normal number of adventitious root primordia. When roots and shoots are cultured together, fewer root primordia are formed on the shoots than on shoots which are isolated from the roots; whereas the number induced on the roots attached to shoots is greater than on the isolated roots. Elongation of the roots is inhibited by these substances, but swelling of the roots occurs to produce what appear to be artificial root nodules. This effect on root culture makes a simple test to distinguish "true" auxins.

THE PRODUCTION AND INHIBITION OF ADVENTI-TIOUS ORGANS AND SOME EFFECTS OF GROWTH SUB-STANCE VAPORS. P. W. Zimmerman and A. E. Hitchcock, Boyce Thompson Institute, Inc., Yonkers, N. Y.—In experiments designed to study initiation and inhibition of adventitious organs, disbudded stem cuttings of Hibiscus syriacus were treated with vapors of growth substances and placed in moist chambers. Both normal and disbudded, non-treated, cuttings served as controls. Controls with normal buds did not form adventitious shoots while disbudded cuttings initiated numerous adventitious shoots, associated with the region of lenticels or callus. As many as 75 adventitious buds were initiated on one six-inch cutting, the majority arising from the distal region. A few adventitious roots arose from the basal end, some protruding through the lenticels. The upper shoots grew fastest and finally inhibited growth

of other adventitious shoots below. The influence appeared to be of a regulatory nature and due to a natural chemical substance. Cuttings treated with vapors from esters of phenylacetic, indolebutyric, indoleacetic,  $\alpha$ -naphthaleneacetic,  $\beta$ -naphthoxyacetic acids,  $\alpha$ -naphthaleneacetamide, or  $\beta$ -naphthoxyacetamide showed increased callus formation at wounded areas, proliferation of lenticels, retardation or inhibition of adventitious shoots, and induction of adventitious roots associated with proliferating lenticels and callus. The vapors of indole and naphthalene compounds induced roots from upper middle and lower regions of the cuttings, thus disturbing normal polarity and in contrast with adventitious shoot initiation in controls.

COMPARATIVE ROOT-INDUCING ACTIVITY OF IN-DIVIDUAL SUBSTANCES AND MIXTURES. A. E. Hitchcock and P. W. Zimmerman, Boyce Thompson Institute, Inc., Yonkers, N. Y.—Combinations of IB (indolebutyric), IA (indoleacetic), and NA (naphthaleneacetic) acids in talc were applied in proportions of 0:4, 1:3, 2:2, 3:1, 4:0, 1:1:1, and 2:1:1 in total concentrations of 2, 5, and 12 mg./g. to cuttings of chrysanthemum, Euonymus, Hibiscus, and privet. IB, IA, NA, and PA (phenylacetic acid) were applied individually (4 to 64 mg./l.) and with additions of 8 or 16 mg./l. of another substance. Increasing the proportion or concentration of a substance most active for a given species generally increased the average number of roots per cutting. IB-NA mixtures were more effective for all species than IB-IA or IA-NA mixtures. Mixtures were more active or active over a broader range than individual substances. The activity of IB or NA solutions (4 to 28 mg./l.) was increased by the addition of 8 or 16 mg/l. of a substance which individually showed little or no activity (PA) up to 64 mg./l. These results are not explainable on the basis of a proportional additive effect, dilution, or inactivation. The effectiveness of mixtures over a broader concentration range without injury and for more species as compared with single substance preparations indicates a possible practical use of such mixtures for rooting cuttings.

FURTHER STUDIES ON THE VEGETATIVE PROPAGA-TION OF SOME GYMNOSPERMS, WITH INDOLE ACETIC ACID. Albert L. Delisle, College of William and Mary, Williamsburg, Va.—Experiments were made on rooting cuttings of some forest and cultivated Gymnosperms, which included representative members of all the tribes of the Coniferales. Particular emphasis was placed on Abies concolor, Abies pectinata, Abies koreana, Picea pungens, Picea Omorika, Sequoia sempervirens, Sciadopitys verticillata, Tsuga diversifolia, Taxus spp. and var., Podocarpus neriifolia and Ginkgo biloba. Of the above, with one or two possible exceptions (Ginkgo and Sciadopitys) it was found that auxin greatly stimulated rooting. The rooting medium and especially the time of year at which cuttings were made determined in large measure the percentages of rooting. For most, best results were obtained with cuttings taken in the

late Fall and Winter, and the poorest when taken in mid-Summer. Except in cuttings of *Picea pungens*, a sand and peat mixture was optimal for rooting. A practical method is offered for the successful vegetative reproduction of the above named members of the Coniferales.

THE HORMONE CONTENT OF MAIZE ENDOSPERMS AS DETERMINED BY DIFFERENT EXTRACTION METHods. G. S. Avery, Jr., H. B. Creighton, and B. Shalucha, Connecticut College, New London, Conn.-Endosperms of Canada Flint maize were removed from dormant and germinating grains at following time intervals: air dry dormant seeds, ½ day, 1 day, 3 days, 5 days, and 7 days. Two different extraction methods were used: (1) A known weight of tissue was ground with sand and extracted with (a) chloroform (Thimann, 1934), (b) alcohol (Laibach and Meyer, 1935; Avery, 1939), and (c) water (Chlodony, 1935; Overbeek, 1938); (2) a known weight of tissue was placed directly in ether and allowed to stand overnight at ca. 5°C. (Boysen Jensen, 1937; Overbeek, 1938). In all instances the extract was taken up in water, then mixed with agar and the hormone content determined by the deseeded Avena test (Skoog, 1937). Water extracts give the maximum yield of growth hormone from dormant endosperms and those at all stages of germination. Significantly different amounts are obtained by the various alcohol methods and the chloroform method. The greatest differences in yield by the various extraction procedures are found in the first 24 hours of germination. Subsequent differences in yield are not as great, but regardless of method, the yield decreases as germination progresses. At the end of seven days very little growth hormone can be detected by any of the methods used.

Growth hormones and heterosis. G. S. Avery, Jr., H. B. Creighton, and B. Shalucha, Connecticut College, New London, Conn.—One possible approach to a physiological explanation of hybrid vigor is through a study of growth hormone content of (1) dormant seeds, (2) seedlings, and (3) older plants which exhibit heterosis. Preliminary studies on dormant endosperms of selected inbred lines of maize show no characteristic relationship in hormone content between parents and hybrid, on a per endosperm basis. On the basis of hormone content per gram of endosperm, the F<sub>1</sub>s are intermediate between the parents.

AUXINS OF HYALOPTERUS ARUNDINIS AND OF ITS HOST. George K. K. Link and Virginia Eggers, University of Chicago, Chicago, Ill.—Comparative quantitative and qualitative studies were made of the auxins of the aphid Hyalopterus arundinis and of the leaf of Phragmites communis on which it feeds. On the basis of wet weight, the ether extract of the aphid in Avena coleoptile tests is 7–25 times, and on the basis of dry weight, 10–37 times more potent than the leaf extract. Per gram of water, the aphid extract is 3–18 times more potent than that of the leaf. Water, acid, and alkali refluxing, together with color tests of the extracts, indicate that the leaf and

aphid extracts each contains the same kind of auxins but in different proportions. Auxins which behave like indole-acetic acid are very much more abundant in the aphid extract. This difference may have its basis in auxins of the honeydew. In view of the fact that sections of the leaf indicate that the aphid derives most of its food from the phloem, the results may indicate that the phloem is the main site of auxins in the leaf of *Phragmites communis*.

DISTRIBUTION OF AUXIN IN SUBTROPICAL FRUIT PLANTS. William C. Cooper and Kenneth R. Knowlton, U. S. Subtropical Fruit Research Station, Orlando, Fla.—Using Van Overbeek's ether extraction method and Went's Avena test, auxin determinations were made on different parts of Citrus and pineapple plants In Citrus the main center of auxin production appeared to be in the growing bud with its embryonic leaves, old leaves producing little or none. The developing fruit also produces auxin. The auxin in the stem below a fruit or below a flush of new growth was shown to be supplied by the fruit or the flush growth. In the pineapple the center of auxin production appears to be in the embryonic etiolated leaves in the heart of the plant. The ethylene treatment to induce blooming in the pineapple had no marked influence on the distribution of auxin in the plant.

PRODUCTION OF AUXIN BY TOBACCO CALLUS CULTURED IN VITRO. Folke Skoog, Harvard University, Cambridge, Mass.—A tobacco callus culture obtained from Dr. Philip White has been propagated on his synthetic liquid and solid media over a period of seven months in the light, and others for five months in the dark. Determinations of auxin made at successive stages of growth of the cultures show that the callus synthesizes auxin both in light and in darkness. The obtainable amounts of active substance vary with cultural conditions and with the age of the cultures.

Some effects of wounds and wound hormones. Carl D. LaRue, University of Michigan, Ann Arbor, Mich.—Bacterium tumefaciens produces large tumors on leaves of Kalanchoe rotundifolia. If inoculated leaves are wounded repeatedly by needle pricks the tumors grow much more rapidly than on unwounded leaves. Hormone extracts prepared according to Bonner's method and applied in lanolin or by injection, gave similar results. Tumor tissue was induced by wound hormone extracts, but definite tumors did not form. Periderm formation was induced in unwounded stems of Coleus by the application in lanolin of extracts containing wound hormones. Tyloses are readily induced in young twigs of Morus alba by wounding. They have been produced also by placing the bases of long shoots in a solution containing wound hormones. Control plants developed tyloses only near the basal cut, but those in the wound hormone solution produced tyloses far up the shoots. Living twigs of Hibiscus placed in nutrient solutions with sugar stimulate growth of cells from intumescences of the Hibiscus rosa-sinensis. In the absence of living twigs, growth is secured by the addition of extracts containing wound hormones. Wounding induces root formation in petioles of Coleus, stems of willow, Mentha arvensis, and Sedum sp. Extracts containing wound hormones give similar results.

THE INFLUENCE OF THE STAGE OF THE REST PERIOD ON ROOTING AT THE CUT SURFACE OF POTATO TUBERS. John D. Guthrie, Boyce Thompson Institute for Plant Research, Inc., Yonkers, N. Y.—Pieces of old or non-dormant potato tubers form roots at the cut surface more readily than pieces of freshly harvested or dormant potato tubers when treated with neutralized indole-acetic acid. Freshly harvested tubers rendered non-dormant by treatment with ethylene chlorohydrin form roots more readily than untreated controls.

FURTHER STUDIES ON GROWTH SUBSTANCES IN RE-LATION TO THE MECHANISM OF THE ACTION OF RADIA-TION ON PLANTS. H. R. C. McIlvaine and H. W. Popp, The Pennsylvania State College, State College, Pa.—Previous studies (Jour. Agr. Res. 57: 931-936. 1937) were continued with particular reference to the action of regions of the visible spectrum. Brassica Rapa L. seedlings were grown for 31/2 or 7 days, and periodically irradiated under varying conditions. The sources of radiation were (a) daylight, (b) a 500-watt Mazda lamp, (c) a G. E. mercury vapor lamp in glass, and (d) a mercury vapor lamp in quartz. Corning glass filters were used, and, where possible, exposures were such as to equalize the total energies reaching the plants. Exposures to varying conditions of daylight and darkness were also made. At the end of the series of treatments the amounts of growth substance in the seedling tips were determined by a modified Went Avena curvature technique. Records of the mean heights of the seedlings indicated a positive correlation between seedling height and the amount of growth substance evidenced in the test. In all cases, results showed that when seedlings are subjected to the shorter visible wave lengths of radiation, the height is less, and there is a smaller amount of growth substance present. Two series of experiments indicated that the growth substance is inactivated to an appreciable extent by daylight, and that it tends to accumulate in darkness.

Note regarding trimethylamine as a plant sex hormone. Lewis H. Flint and Fred McGoldrick, Louisiana State University, University, La.—The injection of potato tubers with aqueous solutions of trimethylamine, carried out as a student's problem in a course in advanced plant physiology, gave results of unusual interest relating to the differentiation of flower buds, the production of blooms and the development of secondary flowering from adjacent axillary shoots. The results obtained tended to confirm those reported by Professor Havas of Belgium in the Science News Letter of November 19, 1938, concerning the efficacy of trimethylamine as a sex hormone.

MAINTAINING A HIGH POTENTIAL GROWTH RATE IN AVENA COLEOPTILES BY PRE-TREATMENT WITH AUXIN. Charles L. Schneider, Harvard University, Cambridge, Mass .- If Avena coleoptiles are pre-treated with low concentration of auxin, then on subsequent treatment with high concentration of auxin the maximal growth rate is as much as fifty per cent higher than that of controls. By using the maximum angle curvature of the Avena test, the increase is enhanced to as much as two hundred per cent. Especially for the maximum angle assay method, there is a sharp optimum curve for the concentration used in pretreatment, the peak being at about 0.02 milligrams of indole-3-acetic acid per liter of agar, that is, at the concentration giving about ten degrees curvature in the Avena test. This kind of pre-treatment is to be distinguished from the "hemi-auxin" pre-treatment of Went, for it achieves the opposite resultsit increases the maximum angle but not the sensitivity to low concentrations. The effectiveness for pretreatment of chemically different auxins is a function of their activities; for the less active auxins, not only is the minimal effective concentration higher, but also the optimal response lower.

HISTOLOGICAL AND ANATOMICAL CHANGES INDUCED BY INDOLE-ACETIC ACID IN ROOTING CUTTINGS OF PINUS STROBUS. Albert L. Delisle, College of William and Mary, Williamsburg, Va.—Cuttings and

brachyblasts from 4-year-old seedlings root readily with auxin treatment. The hormone causes great increase in the size of the cuttings by stimulating cell division and cell enlargement in certain tissues. The cells of the cortex, and those still remaining of the pericycle, initiate mitotic divisions, soon obliterating the cortical canals by the pressure of the adjacent dividing cells, thus contributing largely to the increase in the diameter of the cutting. A periderm is produced subepidermally, and this gives rise to the callus. The cambium is stimulated to form much secondary tissue, consisting of xylem, phloem and parenchyma. Cambial activity, however, is not uniform throughout. Opposite a congerie of rays, adjacent to the leaf trace, cushions of meristematic cells appear which continue dividing, and soon produce the root primordia which by further cell divisions push through the phloem, cortex and periderm, to the outside. The pith is unchanged. Differences in rooting ability between corresponding cuttings of young and old trees seem largely of a physiological nature. Similarly, auxin treated brachyblasts of young and old trees show marked differences in rooting. Unlike rooted cuttings, rooted brachyblasts fail to survive unless adventitious buds have previously been caused to develop in them.

### SYSTEMATIC SECTION

Abstracts of the Papers Presented before the Systematic Section of the Botanical Society of America, Columbus, Ohio, December 28 to 30, 1939

Notes on the Michigan algae. Alton H. Gustafson, Williams College, Williamstown, Mass.—A number of additions to the algal flora of Michigan have been made. Summary records of the algal population including data from several previously uncited papers are assembled. Comparisons are made with the flora of other regions, especially that of Massachusetts.

NEW MOTILE ALGAE FROM NEW JERSEY. Harold C. Bold and Tracy E. Hazen, Columbia University, New York, N. Y.-In collections from a small pond in New Jersey the authors found two motile organisms which appear to be new. They are both of primitive organization since they lack a firm cell wall; they are, however of very different affinities. The first clearly belongs to the class Euglenophyceae and is probably related to the genus Eutreptiella. It differs from Euglena in the possession of two flagella and in the absence of a "gullet" and stigma. Under certain conditions its metaboly is so pronounced that the movement can be considered almost amoeboid. The second organism is a member of the class Chlorophyceae, family Polyblepharidaceae and is probably a new species of the genus Tetrachloris Pascher and Jahoda, which genus has not been reported before from the United States. The present species is significant in that it brings together characters found in diverse genera and is therefore probably more generalized. This genus Tetrachloris may well be regarded as ancestral to the well known Carteria.

A NEW RECORD OF DISTRIBUTION FOR THE GENUS OF OCCLADIUM. Glenn C. Couch, Ohio State University, Columbus, Ohio.—The range of distribution in this country for the algal genus Oedocladium has appeared to be limited to the Atlantic Coastal States. The discovery of the genus in the Boston Mountains of Arkansas greatly extends its range.

AN OSMUNDA HYBRID. R. M. Tryon, Jr., Gray Herbarium, Cambridge, Mass.—Three sheets of Osmunda in the Gray Herbarium have been identified as O. Claytoniana L. × regalis L. var. spectabilis (Willd.) Gray. This is the first instance the author has been able to find of a hybrid in the genus Osmunda. The hybrid has characters of both parents, and some intermediate between them. Also, many of the sporangia are abortive.

THE PALMACEAE: A UNIQUE TAXONOMIC PROBLEM. Miriam L. Bomhard, U. S. Forest Service, Washington, D. C.—An outline chart of pertinent data and the minimum herbarium requirements necessary for the accurate identification of palms.

A NEW SPECIES OF HARTMANNIA. W. H. Horr, University of Kansas, Lawrence, Kan.—Closely resembling H. speciosa (Nutt.) Small, the plant has been collected in eastern Kansas and western Mis-

souri, the main difference being that it is smaller than *H. speciosa* and that the flowers open pink and fade pink. Ten years of reproduction from seeds have brought no noticeable changes.

DESCRIPTIVE METHOD OF LINNAEUS' SPECIES PLANTARUM. Henry K. Svenson, Brooklyn Botanic Garden, Brooklyn, N. Y.—A brief analysis of the components of the Linnaean "descriptions" and relationship to pre-Linnaean works.

A NEW BEGINNING DATE FOR BOTANICAL NOMENCLATURE. Louis Cutter Wheeler, University of Missouri, Columbia, Mo.—Such a burden of taxonomic and nomenclatural synonymy has accumulated since Linnaeus' Species Plantarum that it is time to consider a new starting date for Botanical Nomenclature. To eliminate the present accumulation of useless synonymy and impose a simplified nomenclature on the science of botanical taxonomy within a single generation would require a second Linnaeus.

A series of uniform monographs, much like Das Pflanzenreich, but executed with strict regard for the Rules of Botanical Nomenclature and the type concept, would be bibliographically the most convenient, and most likely to be universally accepted after the approval of the work by an international body of systematists. Each monograph would establish a new starting date for the nomenclature of the group treated. The change of beginning dates must be voluntarily accepted rather than thrust upon us by any man or small group of men. International participation in the basic monographs would encourage general cooperation. There are many problems to solve before any plan for a new beginning date can be put into operation, but now is the time to begin. Perhaps by the end of the second century of binary nomenclature we shall have commenced clearing our nomenclatural attic.

A STATISTICAL APPROACH TO YUCCA WHIPPLEI. Carl Epling and A. L. Haines, University of California, Los Angeles, Calif.—A method of field study, based upon that employed by Anderson on Iris, is described. The geographic variation of Yucca Whipplei is analyzed and five geographic races or subspecies are described.

Variations of ophioglossum vulgatum. Robert T. Clausen, Cornell University, Ithaca, N. Y.—As the result of the study of 555 lots of specimens of Ophioglossum vulgatum L., there seems no sound basis for the segregation of subspecies correlated with geographical distribution. The characters available for such segregation appear not fundamental. Shape and size of sporangia vary with the age of the fertile segment. Presence or absence of a basal sheath depends on the degree of weathering (rotting) of the leaf stalk of the previous season and, in the case of herbarium specimens, on the degree of

washing to which the plants have been subjected. Translucence of the blade depends on age. Shape of the blade appears as the best character available, but this is scarcely sufficient for subspecific segregation. Professor Fernald, in a recent publication, the positiveness of which would seem unlikely had it been based on vast series of plants from throughout the range of the species, recognized four varieties, but these several variations occur too generally, both in the Old and New Worlds, to make practical their recognition as geographical races.

VIBURNUM PUBESCENS, A POLYMORPHIC SERIES. H. A. Gleason, New York Botanical Garden, New York, N. Y.—V. pubescens is primarily a coastal plain derivative of the Appalachian V. dentatum, varying greatly in the size, shape and texture of its leaves and the distribution and amount of pubescence. It also occurs inland, where it has presumably

hybridized with Viburnum molle.

ORIGINS AND RELATIONSHIPS OF THE FLORA OF A BARRIER RANGE OF CALIFORNIA. Joseph Ewan, University of Colorado, Boulder, Colo.-The San Gabriel Mountains, rising chiefly in Los Angeles County, are a fault-block barrier range, sixty miles long by five to twelve miles wide, lying between the coastal plain and the Mohave Desert. Its flora represents seven components, viz., panarctic, Sierran, Monican, Mohavan, Mexican, Rocky Mountain, and endemic elements. The panarctic element is the weakest today, whereas the Sierran is the strongest. The endemic group includes twelve species and nine subspecies; these have affinities with the Bernardine region to the south and the Coast Ranges to the north, but most often represent plant aborigines which have developed in situ, this range being open for population before adjacent areas. The geomorphogeny of the range has played a decisive part in the history of the flora, strongly delimiting the species groups within the range so that eight floristic subareas may be recognized, each with a distinctive geologic history. There are manifest floristic relationships with the Santa Monica, Tehachapi and San Bernardino ranges and also with the distant Santa Lucia and Napa ranges, and the Rocky Mountains via Great Basin connections.

Some problems of plant distribution in Northwestern washington. W. C. Muenscher, Cornell University, Ithaca, N. Y.—Results of field studies made during the summers of 1937 and 1939, indicate that the distributions of many plants west of the Cascade Mountains are limited more by the action of climatic and physiological factors than by physical barriers against migration.

Phytogeographical notes on the arbuckle mountains of oklahoma. Milton Hopkins, University of Oklahoma, Norman, Okla.—In the last two years the identity of numerous plants formerly thought not to occur north of Texas has been ascertained. Their discovery in this calcareous area lends additional evidence to the theory that the flora here is an ancient one closely related to that of the Edwards Plateau of southwestern Texas which is also

of calcareous composition. Previously, few plants were known which were common to both regions of limestone but recent studies have added, among numerous others, Cercis reniformis, Quercus texensis, Fraxinus texensis, Rhus Copallina var. lanceolata, Psoralea Reverchonii and Abutilon incanum.

THE TAXONOMY AND DISTRIBUTION OF THE GENUS LYCOPERSICON. Cornelius H. Muller, Bureau of Plant Industry, Washington, D. C.—The tomatoes, comprising the genus Lycopersicon, are very closely related to the genus Solanum, but the two genera are readily distinguished from one another. The species of Lycopersicon fall naturally into two subgenera, the edible red-fruited species and the unpalatable green-fruited species. The green-fruited group is confined to western South America while the red-fruited group has been spread widely as a result of cultivation. Evidence points to the conclusion that Lycopersicon esculentum var. cerasiforme, the cherry tomato, is the wild prototype of the common Lycopersicon esculentum of horticulture.

Taxonomy of symphoricarpos. George Neville Jones, University of Illinois, Urbana, Ill.—A genus of the Caprifoliaceae with about 15 species, one Chinese, the others North American and distributed from Alaska to Guatemala. The morphological characters of taxonomic and phyletic value are color and size of fruits, shape and size of corollas, leaf-shape, pubescence, habit of plant, and whether prostrate or erect. This is a report of a monographic study begun at the Arnold Arboretum of Harvard University in 1938, and based, in part, upon an examination of nearly 5,000 sheets of preserved material from the

principal North American herbaria.

Hedyotis (Rubiaceae) and its relatives in america. F. R. Fosberg, Bureau of Plant Industry, Washington, D. C.—A preliminary survey of generic relationships within the tribe Hedyotidae (Rubiaceae) indicates three possible treatments: (1) To recognize all apparently natural groups of species as distinct genera. (2) To recognize the major ones as genera, appending the smaller or less distinct groups wherever they do least violence to the generic lines. (3) To consider the whole aggregation, excepting certain very aberrant groups, as a single large genus, Hedyotis. The various subordinate groups would then be arranged as subgenera, sections, etc., in as nearly a natural, phylogenetic scheme as possible.

For various reasons, principally lack of profound structural differences between the groups, the latter course is here adopted. Accordingly, the American groups, segregated by various authors as Oldenlandia, Kohautia, Clavenna (Lucya), Anotis, Houstonia, Arcytophyllum, and probably Teinsolen, may be reunited with Hedyotis. Dentella is maintained as a distinct genus. Lipostoma and its recently described segregates Standleya and Bradea, until their obvious connection with Coccocypselum can be investigated with more abundant material, are also maintained as separate. On the basis of these ge-

nera, the position of Coccocypselum in a different tribe is questioned.

Contrary to most recent usage, the name Hedyotis L., according to the International Rules, must be maintained for the aggregate genus, as it was the one selected by J. E. Smith (1811), the first worker to combine Hedyotis L., Oldenlandia L., and Houstonia L. into one genus.

THE AREAS OF CONCENTRATION AND ENDEMISM OF THE NEW WORLD LABIATAE WITH REFERENCE TO THE OLD WORLD CENTERS. Carl Epling, University of California, Los Angeles, Calif.—Such areas are illustrated and tentative conclusions are drawn as to their interrelationships, which appear to lie wholly North and South. The relationship with the Old World centers appears to be across the North Atlantic.

GEOGRAPHICAL DISTRIBUTION OF THE OCHNACEAE WITH SPECIAL REFERENCE TO GENERIC SEGREGATION IN SOUTH AMERICA. John D. Dwyer, Fordham University, New York, N. Y .- The family Ochnaceae is limited to tropical Africa and Asia as well as to tropical America. While the African and Asiatic genera are few, the number of species greatly exceeds those of meridional America. Distributional mapping in South America indicates that the comparatively numerous genera of the Ochnaceae are localized. These narrow distributional centers compare favorably with the structural characters that mark the localized genera. The importance of distributional mapping is essential to an understanding of the framework of this small but scattered family.

Paleontology of plants studied without fossils. Walter T. Swingle, Bureau of Plant Industry, Washington, D. C.—Paleontology is commonly defined as the science of life in past geologic periods, based on the study of fossil organisms, but much can be learned of the ancient status and subsequent evolutionary changes of plants not yet found as fossils by what may be called paleophylogeny.

In connection with a study of all known genera and species of the citrus subfamily (Aurantioideae-Rutaceae) I found that several genera related to Citrus reached Australia some 25 million years ago while it still had land connection to the north, and we can follow their evolutionary development since then. Micro-citrus, closely related to Citrus, is widely distributed in northeastern Australia and has one species in near-by New Guinea. The four Australian species of this genus represent three very distinct lines of development. Another related Australian genus, Eremocitrus, has, since the Late Cretaceous or Early Eocene, become, under semi-arid climatic conditions, a pronounced xerophyte, strikingly different from Citrus in appearance but still able to hybridize freely with it. Other genera of Aurantioideae, and of other plant families when studied in paleophylogenetic perspective, even without fossil remains, can be restored substantially as they were tens of millions of years ago; we can even see how they have evolved subsequently at strikingly different speeds.

CONTINENTAL DISPLACEMENT AND ITS RELATION TO THE FLORAS OF NORTH AMERICA. W. H. Camp, New York Botanical Garden, New York, N. Y.— Although Continental Displacement is as yet incompletely understood and subject to a different interpretation both as to mechanics and sequence of events from that of the original Wegener hypothesis, it affords the botanist a certain comfort in his study of the broader aspects of plant distribution not found in the doctrine of "land bridges."

It is held that the South American-African land masses were sufficiently close to be mutually communicative during the Mesozoic and that the majority of the basic families of flowering plants evolved there (particularly in South America) during that time; that the union between these closely associated land masses and Holarctica (the single Asia-North America-European mass), just prior to the Cretaceous, permitted the migration of these plants into what is now the Northern Hemisphere. The northward displacement of the earth's major land masses explains the presence of tropical and sub-tropical plant fossils in the Arctic, as well as the Pleistocene glaciations.

It is further held that Holarctica finally disintegrated during the late Tertiary and that Europe (the eastern segment) broke away from the midportion (North America) and was joined with the western segment (Asia) no earlier than the Pleistocene.

A SYMBOLIC METHOD OF REPRESENTING AND COMPARING CLIMATES FOR PHYTOGEOGRAPHIC STUDIES. Henry T. Darlington, Michigan State College, East Lansing, Mich.—Formulas are developed to indicate the essential characteristics of the climates of various regions. It is shown how these formulas may be used in making comparisons between various phytogeographic areas, such as deciduous forest, narrow sclerophyll, grass lands, etc. The year is divided into a number of intervals and relative temperatures and precipitations are related in such a way as to give a picture of the essential features of the climate that determine the type of vegetation.

WOOD ANATOMY AND TAXONOMY IN THE RHUS COMPLEX. Charles Heimsch, Harvard University, Cambridge, Mass.—In Barkley's recent monograph concerning the North American species of the Rhus complex, these plants are grouped under six genera: Actinocheita, Metopium, Malosma, Cotinus, Rhus and Toxicodendron. The anatomy of the secondary xylem gives some support to this grouping. Actinocheita, Metopium, and Malosma are diffuse-porous; the other genera are ring-porous. Only Metopium and Malosma have resin canals in the rays. Metopium shows the most abundant paratracheal parenchyma of all the genera, and it is often banded. In contrast to these diffuse-porous genera which can be distinguished individually, Cotinus, Rhus, and Toxicodendron show great similarity in xylem organization. It would seem that, on the basis of xylem anatomy, these ring-porous genera are on approximately the same level of anatomical specialization. This may be due either to parallelism or close affinity

FLORAL ANATOMY OF THE KALANCHOIDEAE. Albert H. Tillson, U. S. Plant Introduction Garden, Glenn Dale, Md.—The floral anatomy of 28 species of the three genera comprising the subfamily Kalanchoideae (Crassulaceae), was studied in order to determine whether the reduction of Bryophyllum and Kitchingia to Kalanchoe could be justified on the basis of vascular anatomy. In all three genera, each of the four petal traces is adnate to the corresponding antepetalous stamen trace as it leaves the floral axis. In Bryophyllum the petal and stamen traces separate almost immediately, while in Kalanchoe and Kitchingia the petal-stamen bundles remain fused for half the length of the corolla tube. This difference in vascular plans remains constant in all species studied, even though the level of insertion of the stamens varies greatly in each of the genera. The validity of the genera Bryophyllum and Kitchingia is supported by this anatomical evidence.

AN ALKALINE BOG IN NORTHWESTERN IOWA. W. A. Anderson, State University of Iowa, Iowa City.—A hanging bog near Silver Lake, Dickinson County, Iowa, is fed by springs with a high concentration of minerals, and supports a very interesting flora. Over fifty species of plants are listed, of which twelve are extremely rare locally but have wide ranges, especially in the Great Lakes-St. Lawrence Valley re-

gion. Comparison is made with similar local bogs, of which this is one of the richest remaining in the highly cultivated State of Iowa.

Preliminary survey of the flora of grand manan island, new brunswick, canada. E. W. B. Chase, Wayne University, Detroit, Mich.—During the summer of 1938 a plant survey was made on the Island of Grand Manan, lying off the coast of Maine in the Straits of Fundy. A considerable collection was made and identified with the assistance of the Canadian botanist, John Adams, who visited the island later in the summer and checked the plants then in bloom. The geologic formations are briefly discussed together with an outline of the work of previous workers. A list of plants will be given together with a brief discussion of ecological factors. Special mention will be made of the survival of forms brought in in ships' ballast.

RECENT TRENDS IN THE DISTRIBUTION OF WEEDS IN KANSAS. Frank C. Gates, Kansas State College, Manhattan, Kan.—During the past half century the number of plants recognized as weeds in Kansas has risen from 209 to 372, of which 54 were not present 50 years ago. Distinctly northward or southward migrations are shown by less than ten plants each. Thirty-one plants, all but 2 native, have spread eastward. The largest number, over 125, including several native as well as introduced weeds, old timers and new arrivals, are spreading westward, while 116 have remained within the limits they had in the past century.
